PREFACE

The experiment discussed in this report was carried on from September, 1952, to May, 1953, at the U. S. Naval Postgraduate School, Monterey, California. The work was done in partial fulfillment of the requirements for the degree of Master of Science and in a desire to improve submarine storage battery performance. The investigators are grateful for the encouragement of Professor Allen E. Vivell and the technical assistance of Mr. Harold Schauer.

SUMMARY

Objective: An investigation of the effects of charging lead-acid storage cells with a pulsating direct current.

General Methods: A charging circuit was designed and constructed to permit charging a battery of three 24-ampere-hour cells with a pulsating direct current, carefully regulated and metered at 2.4 amperes average value, at a frequency variable from 0.2 to 400 cycles per second. The battery was repeatedly cycled under similar conditions except for frequency of the finishing rate charging current, which was varied from 0.5 to 400 cycles. Control charges, with a steady, non-pulsating current, were also conducted. The gas generation, ampere-hour efficiency, and watt-hour efficiency were determined for each charge, and an attempt was made to correlate these with frequency.

Findings: The investigators demonstrated qualitatively that charging a battery with pulsating current improved performance. For Willard ER-24-2 cells, the best results were observed at a frequency of about 0.5 to 1.0 cycles per second. Further tests, employing statistical methods, are necessary to find the reason for this improvement and to determine quantitatively its magnitude.

RESULTS

Objective: An investigation of the effects of changing load-conditions

on the efficiency of a battery direct current.

General Method: A charging circuit was designed and constructed to permit charging a battery of three 15-ampere-hour cells with a pulsating direct current, carefully regulated and metered at 2.4 amperes average value, at a frequency variable from 0.5 to 100 cycles per second. The battery was repeatedly cycled under similar conditions except for frequency of the pulsating wave charging current, which was varied from 0.5 to 100 cycles. Control charges, with a steady, non-pulsating current, were also conducted. The gas generation, temperature-ellipses, and watt-hour efficiency were determined for each charge, and an attempt was made to correlate these with frequency.

Findings: The investigators demonstrated qualitatively that charging a battery with pulsating current improved performance. The efficiency of three 15-ampere-hour cells, the best results were observed at a frequency of about 0.5 to 1.0 cycles per second. Further tests, employing standardized methods, are necessary to find the reason for this improvement and to determine quantitatively its magnitude.

CHAPTER I

PREVIOUS INVESTIGATIONS

An investigation of the effects of a pulsating battery-charging current leads the experimenter into almost virgin territory. The pioneer in the field is F. Dacos of the University of Liège, who summarized his findings in the Revue Universelle des Mines. [3] His experiments compared generator charging of lead-acid cells to rectifier charging. (In a letter to the investigators Dacos stated that he used a 50 cycle per second current and an unfiltered, full-wave dry rectifier.) He concluded that charging with a pulsating current produced "remarkably better" performance than charging with a steady current. In particular, pulsing the current caused:

- (1) Higher efficiencies, both watt-hour and ampere-hour;
- (2) Decreased gassing (by an average of 15% in 100 tests);
- (3) Higher mean voltage on discharge;
- (4) Decreased "shedding" of active material; and
- (5) Increased cell life (by 34% in a single longevity test).
- (6) *Decreased consumption of water.*

Dacos found the shape of the current pulses to be relatively unimportant.

His brief, qualitative explanation of these phenomena will be discussed later in this paper.

The literature revealed no other reference to battery performance as affected by pulsating charging current, even in Vinal's authoritative Storage Batteries [12]. Vinal's discussion of the physical chemistry of the lead-acid cell, however, suggests an attack on an explanation of these results and will be discussed below.

CHAPTER I

INTRODUCTION

An investigation of the effects of a prolonged exposure to the effects of the environment on the behavior of the organism is the purpose of this study. The organism in this case is the human being, and the environment is the physical and social environment. The study is divided into two parts: (1) the effects of the physical environment on the behavior of the organism, and (2) the effects of the social environment on the behavior of the organism. The first part of the study is divided into three sections: (a) the effects of the physical environment on the behavior of the organism, (b) the effects of the social environment on the behavior of the organism, and (c) the effects of the physical environment on the behavior of the organism.

- (4) Effects of the social environment on the behavior of the organism;
- (5) Effects of the physical environment on the behavior of the organism;
- (6) Effects of the social environment on the behavior of the organism;
- (7) Effects of the physical environment on the behavior of the organism;
- (8) Effects of the social environment on the behavior of the organism;
- (9) Effects of the physical environment on the behavior of the organism;
- (10) Effects of the social environment on the behavior of the organism;

The study is divided into two parts: (1) the effects of the physical environment on the behavior of the organism, and (2) the effects of the social environment on the behavior of the organism. The first part of the study is divided into three sections: (a) the effects of the physical environment on the behavior of the organism, (b) the effects of the social environment on the behavior of the organism, and (c) the effects of the physical environment on the behavior of the organism. The second part of the study is divided into three sections: (d) the effects of the social environment on the behavior of the organism, (e) the effects of the physical environment on the behavior of the organism, and (f) the effects of the social environment on the behavior of the organism.

G. W. Jernstedt, of the Westinghouse Electric Corporation, investigated and patented an electroplating process in which the plating current is periodically reversed. In the Westinghouse Engineer [7] he described the circuits and apparatus used, and gave a qualitative theory explaining the improved plating produced by this method. Neither this article, however, nor any of the other references to periodic-reversal, or "PR" plating (see Bibliography) suggested an explanation for the effects of pulsating charging on storage batteries.

Guided by these references and some experience with submarine storage batteries, the investigators decided to conduct an experiment in which a lead-acid battery would be repeatedly cycled, the finishing-rate current being pulsed at different frequencies. Steady current control charges were to be made for comparison. It was hoped to discover whether benefits similar to Dacos' could be obtained if the charging current were pulsed at a frequency on the order of 1 or 2 cycles per second. Varying the field of a conventional submarine main generator, perhaps by a commercial PR electroplating control, could produce such a current, while a higher frequency on the order of 50 cycles would be difficult to obtain. While the improved performance achieved by Dacos would be valuable in any battery, it would be exceptionally desirable in a submarine battery where high performance and minimum gassing are essential. Since the experimental setup could be adapted for higher frequency work, the frequency range was extended from 0.5 to 400 cycles per second.

O. V. Lenz, of the Department of Electrical Engineering, Cornell-

ated and patented as a method of charging in which the charging current

is periodically reversed. In the International Patent [7] is described

the elements and operation thereof, and gives a qualitative theory explaining

the improved plating produced by this method. Without this article, how-

ever, nor any of the other references in periodic-reversal, or "D.C." plating

ing (see bibliography) suggested an explanation for the nature of plating

occurring on storage batteries.

Guided by these references and some experience with plating other

ago batteries, the investigators decided to conduct an experiment in which

a lead-acid battery would be repeatedly cycled, the plating being removed

being pulsed at different frequencies. Heavy current control charges were

to be made for comparison. It was hoped to discover whether benefits similar

lar to those could be obtained if the charging current were pulsed at a

frequency on the order of 1 or 2 cycles per second. Varying the field of

a conventional alternating main generator, powered by a conventional D.C. electro-

plating control, could produce such a current, while a higher frequency on

the order of 50 cycles would be difficult to obtain. While the improved

performance achieved by D.C. would be valuable in any battery, it would

be exceptionally desirable in a submarine battery where high performance

and minimum gasing are essential. Since the experimental setup could

be adapted for higher frequency work, the frequency range was extended

from 0.5 to 500 cycles per second.

CHAPTER II

PROCEDURE

The first step in a study of pulsating-current charging, the investigators decided, should be to determine the effects on cell performance rather than to study electro-chemical phenomena. Several motives prompted this decision:

(1) Unless improved performance were found to exist, there would be little incentive to study the electro-chemical reactions involved.

(2) The background of the investigators was electrical rather than chemical.

(3) Available laboratory facilities lent themselves better to measuring and controlling electrical rather than chemical variables.

It was therefore decided to study the variation with pulse repetition frequency of the following indices of cell performance:

(1) Ampere-hours per charge, and ampere-hour efficiency;

(2) Watt-hours per charge, and watt-hour efficiency;

(3) Gas generation per charge, per watt-hour, and per ampere-hour; and

(4) Duration of charge.

The general scheme was to connect several cells in series and repeatedly cycle the battery. Since variations in ambient temperature were small, temperature was left uncontrolled with the thought that its effect could be neglected. Otherwise all cycles were as nearly identical as possible except that the current during the finishing rate of each charge was pulsed at a different frequency. Average current was kept the same for each charge.

The first step in a study of qualitative research is the identification of the research problem. This is the first step in a study of qualitative research. The identification of the research problem is the first step in a study of qualitative research. The identification of the research problem is the first step in a study of qualitative research.

- (1) The identification of the research problem is the first step in a study of qualitative research.
- (2) The identification of the research problem is the first step in a study of qualitative research.

The second step in a study of qualitative research is the selection of the research method. This is the second step in a study of qualitative research. The selection of the research method is the second step in a study of qualitative research. The selection of the research method is the second step in a study of qualitative research.

- (1) The selection of the research method is the second step in a study of qualitative research.
- (2) The selection of the research method is the second step in a study of qualitative research.
- (3) The selection of the research method is the second step in a study of qualitative research.
- (4) The selection of the research method is the second step in a study of qualitative research.

The third step in a study of qualitative research is the collection of data. This is the third step in a study of qualitative research. The collection of data is the third step in a study of qualitative research. The collection of data is the third step in a study of qualitative research.

Thus any variation in performance among the cycles should have been due only to the variation in frequency.

A program of experimental work was laid out to determine these data. It later turned out to be too ambitious for the time available, and only parts a, b, c, and d were completed. The schedule, with the approximate times of laboratory and shop work required, was:

- a. Design, construct, and test the experimental setup (20 weeks).
- b. Cycle the battery at frequencies of 0.5, 1, 3, 7.8, 20, 40, 100, and 400 cycles. Use square pulses at low frequencies, half wave rectification at higher frequencies. (4 weeks)
- c. Cycle the battery several times with steady current charging for a comparison with step b. (2 weeks)
- d. Investigate reproducibility of results of steps b and c. (1 week)
- e. If step d reveals low reproducibility, repeat steps b and c often enough to obtain an accurate mean for each frequency. A statistical analysis of the results of steps b and c will be required to determine how many additional runs at each frequency are required.
- f. Repeat these steps for different wave shapes including full wave rectification and pulsed field excitation.

The experimental setup was designed along the lines of Figure 1, which shows a simplified block diagram of the equipment. In general, the battery was discharged for a predetermined number of ampere-hours, then fully charged. The charge was considered to be completed when cell voltage ceased to rise. The gas generated in each cell during the finishing rate was collected and measured. Cell current and voltages were recorded. Electrolyte

There was no variation in performance and the results should have been the only

to the variation in frequency.

A number of experiments with the same set of conditions have been

it is found that only in the conditions for the first condition, and only

under a, b, c, and d with conditions, the subjects, with the appropriate

class of laboratory and they were required, that:

a. During, conditions, and that the experimental setup (20 weeks).

b. During the battery of frequencies of 0.5, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 15,

100, and 200 cycles. The results were at low frequencies, half were 200-

distortion at higher frequencies. (10 weeks)

c. During the battery several times with steady current changing

for a comparison with step b. (2 weeks)

d. Investigate reproducibility of results of steps b and c. (1 week)

e. If step d results for reproducibility, repeat steps b and c

often enough to obtain an average result for each frequency. A statistical

analysis of the results of steps b and c will be required to determine how

many additional runs at each frequency are required.

f. Repeat these steps for different wave shapes including full

wave rectification and pulsed field excitation.

The experimental setup was designed along the lines of Figure 1, which

shows a simplified block diagram of the equipment. In general, the battery

was designed for a predetermined number of experiments, then with

observed. The charges were considered to be completed when cell voltage ceased

to rise. The gas generated in each cell during the charging was also col-

lected and measured. Cell current and voltage were recorded. Electrolyte

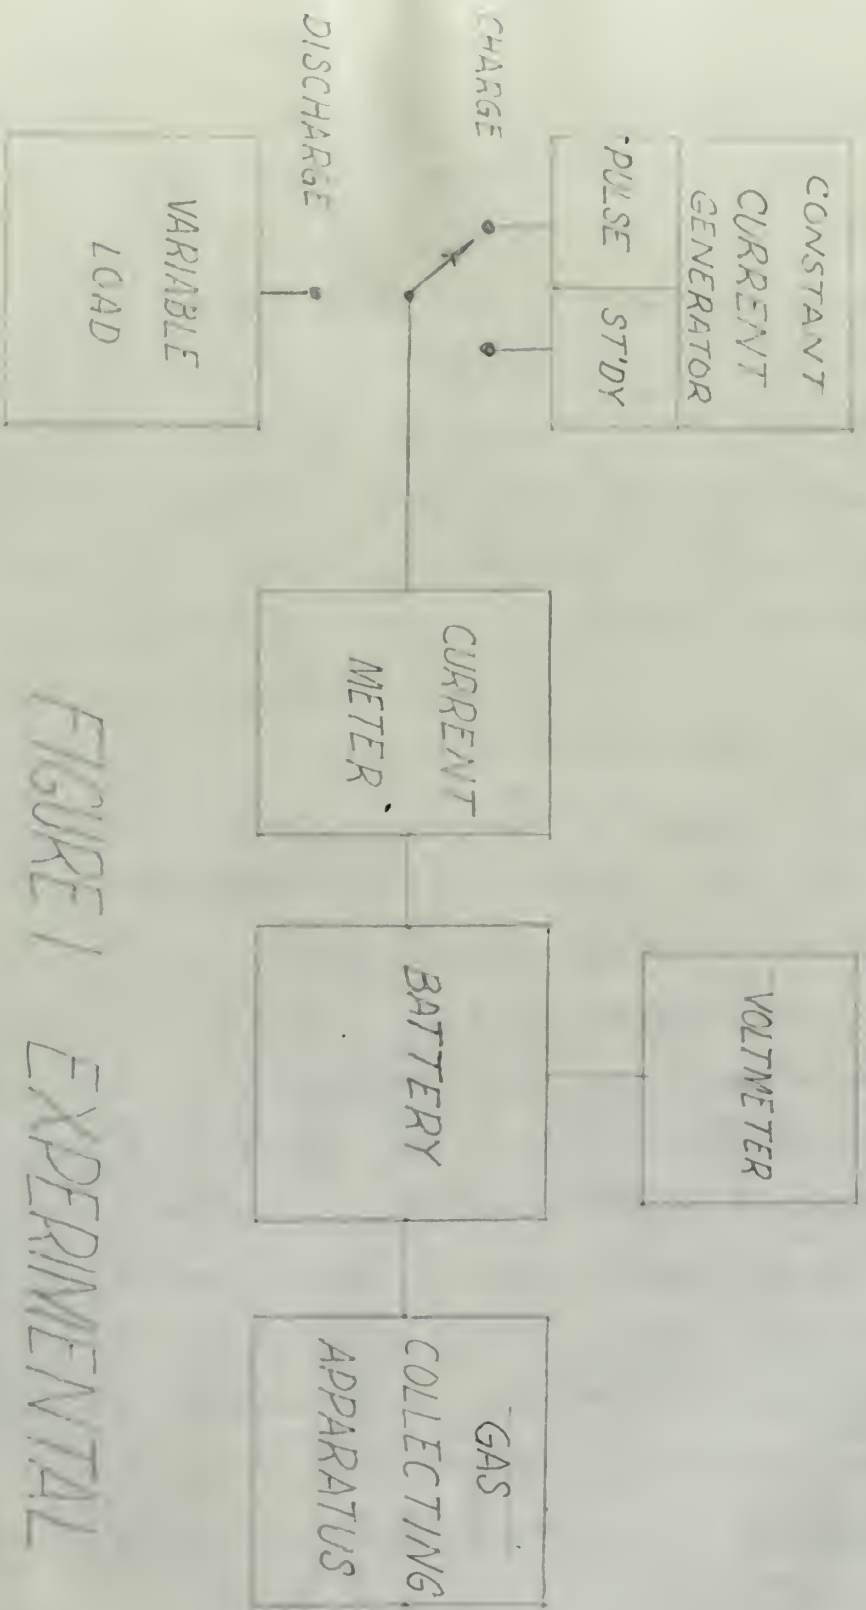

FIGURE 1 EXPERIMENTAL
SETUP

temperature was measured but not regulated.

To regulate and measure these simple data (voltage, current, gas volume, and temperature) required a more complicated arrangement than originally anticipated. Like Topsy it "just grew", until sometimes ten pieces of relatively large rotating machinery had to be run simultaneously. The details of the setup are given at length in Appendix A. As the experiment proceeded, some improvements were made, and some were noted but could not be effected. In particular, the substitution of recording instruments for indicating instruments would have simplified both the regulating and data-taking problems. This and other improvements are more fully discussed in Chapter V.

It was decided to use three Willard Type ER-24-2 cells for the experiment. This cell is a small, plastic-encased, non-spill type having a nominal capacity of 24 ampere-hours with a specific gravity of 1.280. The manufacturer's performance curves are shown in Figure 2 and the Bureau of Ships drawing in Figure 3. A small cell with a low charging current was necessary if square current pulses were to be produced by relaying. A small cell also would generate a relatively small volume of gas and minimize the problem of gas collection and metering and the hazard from hydrogen-oxygen explosions. While realizing that this cell is a far cry from the 5000 ampere-hour submarine cell in which they were primarily interested, the investigators considered that both cells would react similarly to pulsating-current charges. The reactions are the same in each cell, and the voltage, specific gravity, and plate-current density

temperature was recorded by two thermometers.

To regulate and measure these three data (voltage, current, and volume, and temperature) required a more complicated arrangement than originally anticipated. This type of "just moved", until sometimes ten pieces of relatively large rotating machinery had to be run simultaneously. The details of the work are given at length in Appendix A. As the experiment proceeded, some improvements were made, and some were noted but could not be effected. In particular, the substitution of recording instruments for rotating instruments would have simplified both the regulating and data-taking problems. This and other improvements are more fully discussed in Chapter V.

It was decided to use three different types of cells for the experiment. This cell is a small, plastic-covered, non-seal type having a nominal capacity of 30 ampere-hours with a specific gravity of 1.200. The manufacturer's performance curves are shown in Figure 2 and the curves of shape shown in Figure 3. A small cell with a low charging current was necessary if severe current pulses were to be produced by rotating. A small cell also would consume a relatively small volume of gas and minimize the problem of gas collection and rearing and the hazard from hydrogen-oxygen explosions. While realizing that this cell is a far cry from the 2000 ampere-hour automotive cell in which they were primarily interested, the investigators considered that both cells would react similarly to pulsating-current charges. The reactions are the same in each cell, and the voltage, specific gravity, and plate-current density

are similar. Furthermore there was no available equipment for cycling a cell of very large capacity.

The cells were obtained in the charged and dry condition, with the cell openings sealed. All cells were filled with 365 milliliters of reagent grade sulfuric acid of 1.280 specific gravity. After charging for 24 hours, as recommended by the manufacturer, the cells were cycled 4 times. Discharges were at 15 amperes for 45 minutes, or 12 ampere-hours. Charges used two steps of constant current with a starting rate of 6 amperes and a finishing rate of 2.4 amperes. Current was lowered to the finishing rate when any cell reached the gassing voltage determined from the Temperature-Voltage-Gassing curve shown in Figure 4. By the fourth preliminary cycle, cell voltages at end of discharge and at end of charge were substantially constant, and it was considered that no appreciable change of cell characteristics would occur with further cycling.

To be able to fill a hydrometer barrel, it was necessary to keep the electrolyte level about one centimeter above the level line on the cell jar. The gravity of this upper layer of electrolyte changed very slowly, dropping only ten or twenty points during a one-hour discharge. Since gravity readings were not significant, the filling plugs were inserted and sealed with wax after the fourth preliminary cycle. No more gravities were taken until the completion of the experiment, when they were again read, and found to have dropped about 10 points. This small change was assumed to have negligible effect. Hydrometer readings were corrected

are stated. Furthermore there was no suitable equipment for studying

cell of very large capacity.

The cells were obtained in the charged and dry condition, after the

cell operating period. All cells were filled with 200 milliliters of

reagent grade sulfuric acid of 1.880 specific gravity. After charging

for 24 hours, as recommended by the manufacturer, the cells were cooled

4 times. Discharges were at 10 amperes for 25 minutes, or 10 amperes-

hours. Charges used two steps of constant current with a starting rate

of 6 amperes and a finishing rate of 2.5 amperes. Current was lowered

to the finishing rate when any cell reached the limiting voltage deter-

mined from the Temperature-Voltage-Charging curve shown in Figure 4. By

the fourth preliminary cycle, cell voltages at end of discharge and at

end of charge were substantially constant, and it was considered that no

appreciable change of cell characteristics would occur with further cy-

cling.

To be able to fill a hydrometer barrel, it was necessary to keep the

electrolyte level about one centimeter above the level line on the cell

jar. The gravity of this upper layer of electrolyte changed very slowly,

dropping only ten or twenty points during a one-hour discharge. Since

gravity readings were not significant, the filling jars were inserted

and sealed with air after the fourth preliminary cycle. No more gravi-

ties were taken until the completion of the experiment, when they were

again read, and found to have dropped about 10 points. This small change

was assumed to have negligible effect. Hydrometer readings were corrected

FIGURE 6. CHARGING CURRENT PULSE SHAPES

- Notes
1. Scales differ among the traces.
 2. In each case mean current is 2.4 amperes.
 3. Traces below 10 cycles per second by Brush recorder; above 10 cycles by cathode ray oscillograph.

to 80°F/80°F by the curves of Figure 5.

The current pulse shape was chosen as a square wave of equal on and off periods for frequencies below 10 cycles per second. For higher frequencies a half sine wave was used. In both cases the mean value was 2.4 amperes. Figure 5 shows the current wave shapes actually used. In some cases, on and off times were not precisely equal; in others, slot harmonics were prominent. In every case the average value was measured to be 2.4 amperes. Although the same pulse shape, either half-sine or square, would have been desirable for the entire frequency range, practical difficulties prevented it. It proved impractical to operate a relay or switch faster than about 5 cycles per second. When available alternators were run at speeds lower than that corresponding to about 15 cycles per second, it was impossible to generate sufficient voltage. Dacos [3, page 17] stated that

careful trials, made with different forms of rectified alternating current, showed a very slight supplementary benefit in gas evolution when one used 3rd harmonic current.

It was consequently assumed that the square wave and the half sine wave would produce similar results. The "steady" current actually had a small slot ripple, but it was believed that the ripple produced no appreciable difference from a truly constant direct current.

After the fourth preliminary cycle the test cycles were begun. Steady and pulsed runs were conducted in a random order to counteract any effect of progressive changes in the battery with cycling. The test cycles followed the same procedure as the preliminary cycles. The cells were discharged for 45 minutes at 15 amperes, then put on charge at 6

amperes steady current. When the gassing voltage was reached on any cell, the current was dropped to 2.4 amperes and gas collection was begun. The finishing rate current was pulsed or steady depending on whether the run was a test run or a control run. The gas was collected, individually for each cell, over water, and kept at atmospheric pressure by a leveling bulb. No attempt was made, nor was it practicable, to separate the hydrogen and oxygen formed at the negative and positive plates respectively. The gas collected was therefore a saturated mixture of hydrogen and oxygen plus the air initially in the collection apparatus. Difficulty with gas leakage was overcome by sealing the filling caps with wax.

During discharges, voltage readings were recorded at 6 minute intervals. During charge, voltage readings were taken at 12 minute intervals until the charge was almost completed. The temperature correction to voltage, 1.1×10^{-4} volts per degree F., was neglected. For the last hour or so, readings of voltage and gas level were taken at 6 minute intervals. Gas volume was corrected for temperature but not for pressure. As explained in Appendix A, the current pulsations were stopped during voltage readings at the lower frequencies and the current maintained at 2.4 amperes steady until the cell voltages were read. Although this procedure masked somewhat the change in performance due to pulsing, it was accepted as a necessary evil. Since cessation of voltage rise was the criterion for determining the end of the charge, it was essential to measure voltage accurately. A ballistic galvanometer could have been used to read the average of the pulsating voltage, but it would have added complications, especially in

negative charge current. When the limiting voltage was reached on any cell, the current was dropped to 2.5 amperes and the collection was begun. The limiting rate current was raised or slowly decreased as needed to maintain the rate was a fast run or a control run. The gas was collected, initially for each cell, over water, and kept at atmospheric pressure by a leveling bulb. No attempt was made, nor was it practicable, to maintain the hydrogen and oxygen formed at the negative and positive plates respectively. The gas collected was therefore a saturated mixture of hydrogen and oxygen since the air initially in the collection apparatus. Initially with the leakage was overcome by sealing the filling caps with wax. During discharge, voltage readings were recorded at 5 minute intervals. During charge, voltage readings were taken at 15 minute intervals until the charge was almost completed. The temperature correction to voltage, 1.1×10^{-4} volts per degree C., was neglected. For the last hour or so, readings of voltage and gas level were taken at 5 minute intervals. Gas volume was corrected for temperature but not for pressure. An explanation in Appendix I. The current limitations were stopped during voltage readings at the lower limit and the current maintained at 2.5 amperes steadily until the cell voltages were read. Although this procedure raised somewhat the charge in performance due to limiting, it was accepted as a necessary evil. Since cessation of voltage rise was the criterion for determining the end of the charge, it was essential to measure voltage accurately. A ballistic galvanometer could have been used to read the charge of the limiting voltage, but it would have added considerable expense in

maintaining accurate calibration. In any event, the data could be corrected for the amount of time when the current was steady instead of pulsating. An ordinary d'Arsonval movement voltmeter was therefore used for all charges.

Part b of the program was considered completed after runs at 0.5, 1, 3, 7.5, 20, 40, 100, and 400 cycles per second, and part c after 4 steady current control runs. As discussed in Chapter III, it was difficult to reproduce results in the control runs. To discover whether the lack of reproducibility was caused by faulty experimental techniques or was inherent in cell performance, the investigators commenced part d of the program. Five cycles were run under nearly identical conditions, except that electrolyte temperature was allowed to vary over a small range. Each cycle consisted of a discharge at 15 amperes for 10 minutes plus a charge at 2.4 amperes steady current until voltage ceased to rise. Gas was collected as before. Although even a cursory study of the results showed the desirability of more runs, lack of time forced a stop to experimental work. The analysis of results and writing of the report were then undertaken.

CHAPTER III

FINDINGS

The experiment proved several points conclusively and gave somewhat less conclusive answers to several other questions. An incidental conclusion was that the manufacturer overestimated the cell discharge capacity at the 15 ampere rate. According to the curves of Figure 2, the cells should deliver 15 amperes for 71 minutes at 80°F., for 65 minutes at 70°F., or for 60 minutes at 60°F., before cell voltage reached the minimum allowable of 1.65 volts. On one occasion, the cells reached a voltage of 1.62 by the end of a 48 minute discharge at 15 amperes. On another occasion, when the cells were discharged to the low voltage level, they delivered only 80% of rated capacity. The usual voltage at the end of 48 minutes was 1.8, dropping rapidly. Although the discharges were always terminated after 48 minutes, it was exceedingly doubtful whether the cells would have discharged for 17 more minutes without reaching 1.65 volts. A similar conclusion was reached by the Mare Island Naval Shipyard Industrial Laboratory [8] in tests of 12 similar cells. (They were of the same Navy stock number, but manufacturer not specified.) The laboratory found an average ampere-hour efficiency of 94% at the 15 ampere rate, although performance at the 5 minute and 10 hour rates was excellent.

A second conclusion was that fluctuation in cell voltage, when the battery was charged with a pulsating current, decreased as the frequency increased. Voltage ripple, defined as the ratio between voltage fluctuation and mean voltage, decreased from .124 at 0.2 cycles per second

DISCUSSION

INTRODUCTION

The experiment proved several points conclusively and gave some-
 less conclusive results to several other questions. An incidental con-
 clusion was that the manufacturer overestimated the cell discharge ca-
 pacity at the 15 ampere rate. According to the curves of Figure 2, the cells
 should deliver 15 ampere for 17 minutes at 80%, for 15 minutes at 70%,
 or for 60 minutes at 50%, before cell voltage reached the minimum allow-
 able of 1.65 volts. On one occasion, the cells reached a voltage of 1.65
 by the end of a 45 minute discharge at 15 ampere. On another occasion,
 when the cells were discharged to the low voltage level, they delivered
 only 80% of rated capacity. The actual voltage at the end of 15 minutes
 was 1.8, dropped rapidly. Although the discharges were always terminated
 after 45 minutes, it was exceedingly doubtful whether the cells would have
 discharged for 17 more minutes without reaching 1.65 volts. A similar con-
 clusion was reached by the War Island Naval Shipyard Industrial Laboratory
 [3] in tests of 12 similar cells. (They were of the same heavy stock number,
 but manufacturer not specified.) The laboratory found an average cap-
 acity efficiency of 94% at the 15 ampere rate, although performance at the
 5 minute and 10 hour rates was excellent.

A second conclusion was that fluctuation in cell voltage, when the
 battery was charged with a pulsating current, decreased as the frequency
 increased. Voltage ripple, defined as the ratio between voltage fluctu-
 ation and mean voltage, decreased from .124 at 0.5 cycles per second

becoming roughly asymptotic to .025 at frequencies above 2 cycles per second. The actual values are shown in Figures 7 and 8.

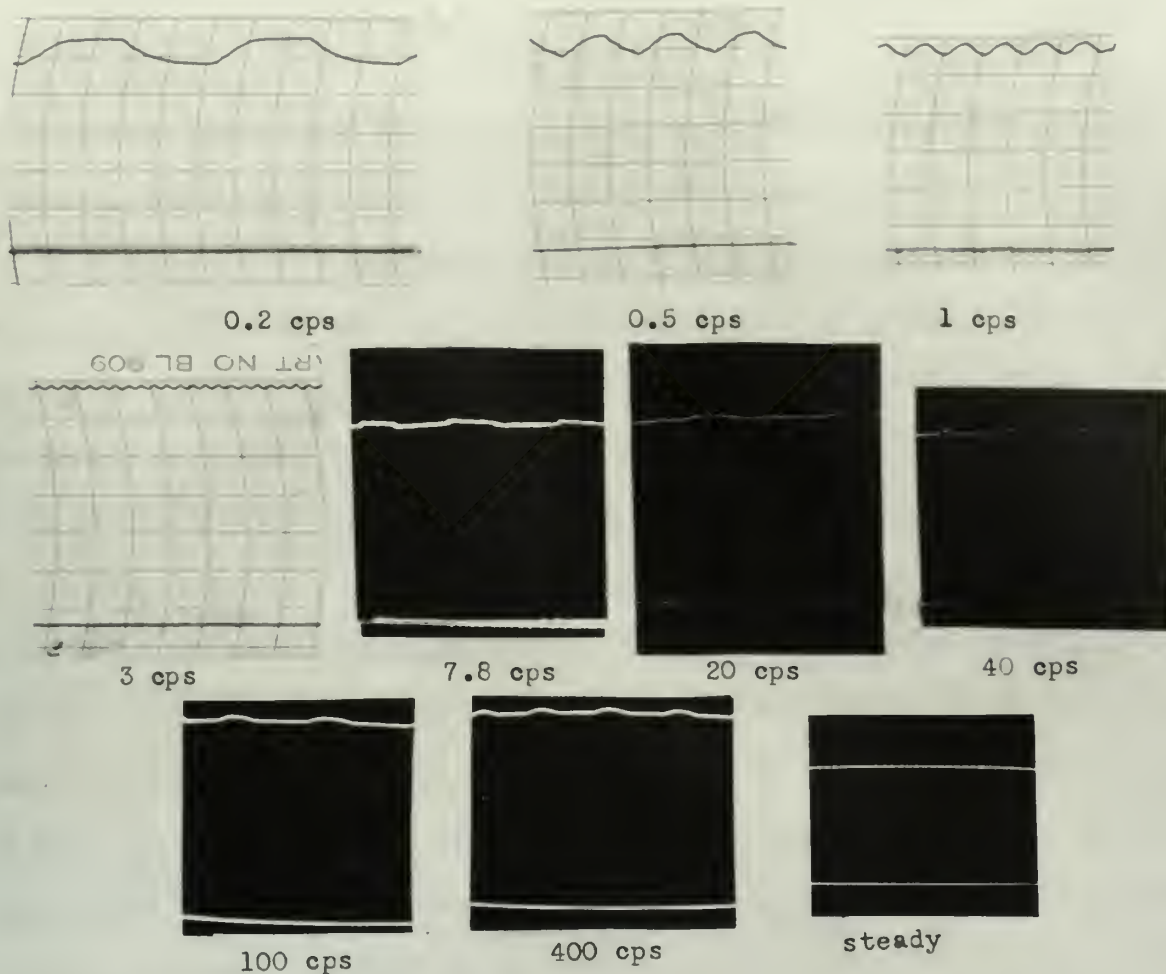

Figure 8. Voltage Ripple

Shapes of the cell voltages and voltage fluctuations are shown in Figure 9, while current shapes are shown in Figure 6 above. Ripple was substantially the same for both current shapes at frequencies above 3 cycles, although the shape of the fluctuation was different. The small, 540 cycle current ripple produced an almost negligible voltage ripple.

A third conclusion is that storage cell performance is not reproducible under ordinary laboratory conditions. Tests run under very similar, if not identical, conditions produced varying results. The investigators were unable to correlate indices of performance with any variable. They were forced to conclude that the indices obtained in this experiment were distributed according to an unknown frequency distribution. The experimentally observed means of these indices cannot be said to equal the true indices. It is possible, however, under certain not unreasonable assumptions, to state a range within which, at a high confidence level, each true index should lie. These confidence limits are shown on the curves

of Figure 10. Since the statistical analysis is rather lengthy, it is discussed in detail in the following chapter rather than here.

A surprising fact was noted when the volume of gas per ampere-hour during the surcharge was compared with that predicted by Faraday's Law. During the surcharge (portion of charge after voltage ceases to rise) all the charge sent through the cell is transmitted by electrolysis of the water of the electrolyte. Since all the PbSO_4 has been transformed into Pb and PbO_2 , there is no other mechanism for current flow. One then expects to generate one equivalent of gas at each electrode for every faraday of electricity sent through the cell. If the hydrogen and oxygen were collected together, one would expect to collect about 715 cubic centimeters of the saturated mixture at 27°C . for every ampere-hour of charge. For all frequencies, however, the volume of gas collected was about 444 cubic centimeters per ampere-hour, 62% of the expected value. (Electrochemists would say that the current efficiency was 62%.) Figure 11 shows the values of gas per ampere-hour. The only explanation is that some of the hydrogen and oxygen have recombined into water before escaping from the electrolyte. The investigators then concluded that some of the gas produced prior to the surcharge must also recombine rather than escape. The volume of gas collected was then a function of two phenomena:

- (1) during the gassing before completion of the charge, part of the current desulfated the plates and the rest electrolyzed the water of the electrolyte,

- (2) part of the electrolytically produced hydrogen and oxygen recombined

of Figure 10. Since the electrical conductivity is rather low, it is dis-

covered in detail in the following chapter rather than here.

A surprising fact was noted when the volume of gas per ampere-hour during the experiment was compared with that predicted by Faraday's law. During the experiment (portion of charge after voltage ceased to rise) all the charge sent through the cell is transmitted by electrolysis of the water of the electrolyte. Since all the H_2O has been transformed into H_2 and O_2 , there is no other mechanism for current flow. One then expects to observe an equivalent of gas at each electrode for every faraday of electricity sent through the cell. If the hydrogen and oxygen were collected separately, one would expect to collect about 17 cubic centimeters of the saturated mixture at 27°C. for every ampere-hour of charge. For all frequencies, however, the volume of gas collected was about 17 cubic centimeters per ampere-hour, 62% of the expected value. (Electrochemists would say that the current efficiency was 62%). Figure 11 shows the values of gas per ampere-hour. The only explanation is that some of the hydrogen and oxygen have recombined into water before escaping from the electrolyte. The investigators then concluded that some of the gas produced prior to the experiment was also recombining rather than escaping. The volume of gas collected was thus a function of the phenomenon:

- (1) During the passage before completion of the charge, part of the current desalted the plates and the rest electrolyzed the water of the electrolyte,
- (2) Part of the electrolytically produced hydrogen and oxygen recombined

bined into water and part escaped. The relative effect of these two phenomena was not determined, but it was concluded that both occurred to some extent.

The lack of reproducibility of indices of performance prevented giving an exact quantitative answer to the question, "How does battery performance vary with frequency of current pulsation?" It was obvious, however, that pulsating charges improved most indices of performance, particularly at low frequencies on the order of one cycle per second. Figure 10 shows graphically the values of the most important indices. The dashed lines in each graph represent the respective means of the steady current control runs, while the dot-dash lines on either side represent the 90% confidence limits for this mean. That is, the probability is 0.9 that the true value of the index lies between the dot-dash lines. A straight line was fitted to the points for pulsating current as the best estimate of the true situation. Confidence limits in the form of a shaded area centered on this line could have been plotted, but the computation is so tedious and the added information so little that this work was not undertaken. In general, the width of this band would be several times that of the control run confidence band. Quantitative statements being out of order, the following qualitative conclusions were reached for the various indices of performance:

Time: Possibly a slight improvement at the lower frequencies.

Ampere-hours: Possibly a slight improvement at the lower frequencies.

Watt-hours: Slight improvement at the lower frequencies.

Gas evolved: Definite improvement at the lower frequencies; little or none above 100 cycles per second.

dined into water and part escaped. The relative effect of these two phenomena
 was not estimated, but it was concluded that both occurred to some extent.
 The lack of reproducibility of indices of performance prevented giving
 an exact quantitative answer to the question, "How does battery performance
 vary with frequency of current pulsation?" It was obvious, however, that
 pulsating current improved most indices of performance, particularly at
 low frequencies in the order of one cycle per second. There is some
 question as to the values of the most important indices. The dashed line in
 each graph represents the respective means of the steady current control runs,
 while the dot-dash lines on either side represent the 90% confidence limits
 for this mean. That is, the probability is 0.9 that the true value of the
 index lies between the dot-dash lines. A straight line was fitted to the
 points for pulsating current as the best estimate of the true situation.
 Confidence limits in the form of a shaded area centered on this line could
 have been plotted, but the construction is so tedious and the added interest
 seen so little that this work was not undertaken. In general, the effect of
 this band would be several times that of the control run confidence band.
 Quantitative statements being out of order, the following qualitative con-
 clusions were reached for the various indices of performance:
Time: Possibly a slight improvement at the lower frequencies.
Current-pulse: Possibly a slight improvement at the lower frequencies.
Self-heating: Slight improvement at the lower frequencies.
Gas evolved: Definite improvement at the lower frequencies; little
 or none above 100 cycles per second.

Gas per ampere-hour and per watt-hour: Decided improvement at all frequencies tested, greatest at the lower frequencies.

Efficiencies: Slight improvement at the lower frequencies.

In summary, the greatest benefits were noted in gas evolution, with slight improvement in other indices.

CHAPTER IV

DISCUSSION OF RESULTS

According to the double sulfate theory, the reaction in a lead acid cell is:

During charge the reaction goes from left to right. According to Vinal [12, page 171] the cell terminal voltage is:

$$V = Ir + 1.87 + \frac{RT}{2F} \ln \left\{ \frac{[\text{Pb}^{++++}]}{[\text{Pb}^{++}]^2} \right\},$$

where

I = current

r = cell internal resistance (virtual)

R = universal gas constant

T = absolute temperature, $^{\circ}\text{Rankine}$.

F = Faraday's constant

$[\text{Pb}^{++++}]$ = concentration of tetravalent lead ions

$[\text{Pb}^{++}]$ = concentration of bivalent lead ions.

It can be shown that the concentration of the tetravalent ion increases and that of the bivalent ion decreases as the charge proceeds, the voltage thus increasing. Cell temperature tends to rise because of I^2r heating as well as because of the heat of this exothermic reaction, and cell voltage is further increased.

Electrolysis of water occurs at a voltage which varies linearly with temperature. As shown in Figure 4 above, the value is 2.35 volts at 80°F

EXPERIMENTAL

connected to the double active theory, the reaction is as follows:

cell 1:

During operation the reaction goes from left to right, according to the

[1], page 171 the cell terminal voltage is:

$$V = E - \frac{RT}{nF} \ln \left\{ \frac{[\text{H}_2\text{O}_2]^{++}}{[\text{H}_2\text{O}]^{++}} \right\}$$

where

E = standard

n = cell terminal resistance (ohms)

R = universal gas constant

T = absolute temperature, $^{\circ}\text{K}$

F = Faraday's constant

$[\text{H}_2\text{O}_2]^{++}$ = concentration of hydrogen peroxide ions

$[\text{H}_2\text{O}]^{++}$ = concentration of water ions

It can be shown that the concentration of the hydrogen ion increases and that of the hydroxyl ion decreases as the reaction proceeds, the cell voltage increases. Cell terminal voltage is the measure of E and the cell as well as decrease of the rate of rate catalytic reaction, and cell voltage is further increased.

Electrolysis of water under a voltage often occurs internally with temperature. As shown in Figure 1, the value is 2.2V at 20°C

and decreases as temperature increases. This voltage is usually reached when about 90% of the ampere-hours discharged have been replaced. By this time the desulfating reaction, which proceeds into the plates layer by layer, has reached almost the mid-plane of the plates. When electrolysis begins, the gas is thus formed in the midst of the active material of the plates. Until all the lead sulfate has been decomposed, part of the current goes into the charging reaction and part goes into electrolysis. When all sulfate has been decomposed, the charge is complete and all further current must cause electrolysis. The escape of the resulting hydrogen and oxygen bubbles is called gassing. These bubbles must escape through the pores of the active material. In doing so, especially at a high rate and at a high temperature, they loosen particles of active material which tend to "shed" or drop to the bottom of the cell as sediment. The capacity of the cell is proportionally reduced, and when the sediment pile grows high enough it may short circuit the plates. The mixture of hydrogen and oxygen creates an explosion hazard. As the bubbles leave the cell they entrain particles of electrolyte which lower cell capacity and corrode ventilation ducting. The energy which goes into electrolysis causes a drop in efficiency. In short, except for mixing the electrolyte, gassing performs no useful purpose and should be minimized. Reduction of gassing leads to safer, more economical operation and longer cell life.

Dacos [3, page 15] explains the reduction of gassing which he obtained as follows:

and decreases as temperature increases. This volume is usually reached when about 90% of the sulphuric acid has been replaced. At this time the desulfurizing reaction, which proceeds into the plates layer by layer, has reached almost the mid-point of the plates. When electrolysis begins, the gas is thus formed in the midst of the active material of the plates. Until all the lead sulfate has been decomposed, part of the current goes into the charging reaction and part goes into electrolysis. When all sulfate has been decomposed, the charge is complete and all further current must cause electrolysis. The escape of the resulting hydrogen and oxygen bubbles is called venting. These bubbles must escape through the pores of the active material. In doing so, especially at a high rate and at a high temperature, they loosen particles of active material which tend to "shed" or drop to the bottom of the cell as sediment. The capacity of the cell is proportionally reduced, and when the sediment has grown high enough it may short circuit the plates. The sediment of hydrogen and oxygen creates an explosion hazard. As the bubbles leave the cell they entrain particles of electrolyte which lower cell capacity and corrode ventilation ducting. The energy which goes into electrolysis causes a drop in efficiency. In short, energy for driving the electrolyte, passing current no useful work is done and should be minimized. Reduction of gassing leads to safer, more economical operation and longer cell life.

Notes [2, page 12] explain the reduction of gassing which is obtained as follows:

.... this reduction in volume of gas comes from the fact that during a charge under pulsating voltage, the voltage is, during a fraction Θ of a half-period, greater than the equivalent mean steady current, and during the rest of the half period, smaller. But, during the latter interval of time, gas stops being evolved while the voltage of decomposition [of water] is not reached, and the ions which have just reached the reacting strata of the active material enter into chemical reaction with the lead sulfate.

Since he investigated only one frequency, Dacos did not consider the effect of changing the duration of his "fraction Θ ". There is no obvious reason why a long non-gassing period should cause more reaction than several short non-gassing periods, although the higher ampere-hour efficiencies noted at low frequencies suggest that this is the case. Solution of this question would require a study using physical chemistry methods. Some of the obvious factors are geometry of the plates, porosity of the active material, temperature, specific gravity, and viscosity of the electrolyte, velocity of ions and gas bubbles, pressure, and current density. In Dacos' opinion,

The behavior of the cell depends essentially on the phenomenon of diffusion.

An investigation of this nature was out of the scope of the experiment.

Vinal's voltage equation, together with the observed variation of voltage ripple, sheds some light on the matter. A step increase of charging current from 0 to 4.8 amperes did not produce a step change in cell voltage, as seen in Figures 6 and 9. With the current level at a constant 4.8 amperes, the voltage gradually approached a maximum. The change in voltage must have been due to a change in one or more of the quantities r , T , and ionic concentrations. It is known that r is not constant and is a function at least of current and condition of charge. In fact Vinal

[12, page 34] states that cell resistance is only a quantity which must be added to R_{external} to satisfy the equations $I = \frac{V_{\text{cell}}}{R_{\text{external}} + r}$

Furthermore he states that the ionic concentrations cannot be measured directly. "T" could hardly be considered to vary significantly under a current pulsing as rapidly as once or twice a second. Therefore the variations in performance might be linked to variations in cell resistance or ionic concentrations. One difficulty with this hypothesis is the constancy of voltage ripple above 2 cycles. Battery performance was not constant over this range.

Although voltage ripple was not measured at frequencies below 0.2 cycles per second, it is possible to predict that it will approach a maximum on the order of 0.25 for frequencies on the order of 20 minutes per cycle for a square wave of 10 minutes at 4.8 amperes and 10 minutes at zero current. This value was computed by noting that the voltage of a fully charged cell drops from about 2.8 to about 2.2 volts within 10 minutes after a charging current of 4.8 amperes is open-circuited. If performance is best at highest voltage ripple, the optimum frequency would then be on the order of 20 to 30 minutes per cycle. (The electroplating industry uses "PR" cycles on the order of 15 seconds plate and 5 seconds deplate.) A minimum practical frequency would be set by excessive shedding that would probably be caused if peak current were maintained for a matter of minutes, even if followed by an open circuit period of equal duration. For example, the prescribed finishing rate for the Willard ER-24-2 cell is 2.4 amperes. Suppose that a "pulsating" current of 4.8 amperes for 30 minutes followed by open circuit for 30 minutes, etc., were used for the finishing rate.

[12, page 10] states that cell resistance is only a quantity which must

be added to the resistance of the electrolyte to give the total resistance.

Furthermore he states that the total resistance cannot be considered directly. "It could hardly be considered as very slightly under a constant value as it varies as often or twice a second. Therefore the variations in performance might be limited to variations in cell resistance or local concentrations. One difficulty with this hypothesis is the constancy of voltage ripple above 2 cycles. Battery performance was not constant over this range.

Although voltage ripple was not measured at frequencies below 0.5 cycles per second, it is possible to predict that it will approach a maximum on the order of 0.5% for frequencies on the order of 50 minutes per cycle for a square wave of 10 minutes at 1.8 amperes and 10 minutes at zero current. This value was computed by noting that the voltage of a fully charged

cell drops from about 2.8 to about 2.2 volts within 10 minutes after a charged current of 1.8 amperes is discontinued. If performance is best at highest voltage ripple, the optimum frequency would then be on the order of 20 to 30 minutes per cycle. (The electrolyte conductivity was 100 ohm-cm on the order of 15 seconds at 1.8 amperes and 5 seconds at zero current.) Practical frequency would be set by successive shorting that would drop slightly be caused if peak current were maintained for a matter of minutes, even if followed by an open circuit period of equal duration. For example, the predicted limiting rate for the Miller 22-2-2 cell is 2.5 amperes. Suppose that a "pulsating" current of 1.8 amperes for 30 minutes followed by open circuit for 30 minutes, etc., were used for the limiting rate.

Although the average current would be 2.4 amperes, excessive gassing would undoubtedly occur during the 30 minute "on" period with loss of active material through shedding. The same considerations would prohibit a pulse shape such as 24 amperes for one second followed by open circuit for 9 seconds. Although average current would be 2.4 amperes, excessive gassing and shedding would again result. Cell life could probably be reckoned in pulses rather than in months. For optimum results, three conflicting requirements evidently must be balanced:

- (1) a large voltage ripple;

- (2) a period long enough to produce a large ripple but not so long as to produce damaging gassing; and

- (3) not too high a peak current.

An educated guess is that the best frequency would be in the vicinity of 0.01 cycles per second (period of 100 seconds).

Dacos did not observe recombination of hydrogen and oxygen during the gassing period; he collected almost exactly the volume predicted by Faraday's Laws. In the present experiment only 62% of the predicted volume was actually collected; the other 38% recombined into water before escaping from the electrolyte. The Willard non-spill cells contained highly absorbent separators which undoubtedly affected the rate of diffusion and gas escape. Dacos' cells, 42 ampere-hour Tudor type BVM 3, probably contained conventional separators which left a considerable volume of electrolyte unabsorbed. Recombination of the gas can possibly be related to this difference in construction.

Although the average current would be 2.5 amperes, excessive heating would

undoubtedly occur during the 20 minute test period which would be of little
material through heating. The same considerations would apply to a pulse

shape such as the square wave for one second followed by seven minutes for 9
seconds. Although average current would be 2.5 amperes, excessive heating
and shedding would again result. Cell life would probably be reduced in
pulse rather than in steady. For optimum results, three possibilities are
equipment evidently may be balanced:

- (1) a large voltage source;
- (2) a period long enough to produce a large pulse but not so long as
to produce excessive heating; and
- (3) not too high a pulse current.

An obvious factor is that the test frequency would be in the vicinity of
0.01 cycles per second (period of 100 seconds).

James did not observe recombination of hydrogen and oxygen during the
pulsing period; he collected almost exactly the volume predicted by Far-
aday's law. In the present experiment only 65% of the predicted volume
was actually collected; the other 35% recombined into water before escap-
ing from the electrolyte. The dried non-gaseous cells contained slightly
excess hydrogen which undoubtedly affected the rate of diffusion and
the escape. These cells, the hydrogen-ion theory type IV, probably con-
tained concentrated electrolyte which left a considerable volume of electro-
lyte unabsorbed. Recombination of the gas can possibly be related to this
difference in concentration.

Since Dacos observed no recombination, his reduction of gassing must have been due entirely to reducing electrolysis. The present experiment demonstrated the reverse; ampere-hour efficiency was only slightly improved by pulsing; hence electrolysis was only slightly diminished. The main cause of reduction in gassing must then have been the reaction of hydrogen and oxygen to form water. This reaction would not be explosive if it proceeded continuously, since it could then liberate energy at no higher rate than it was supplied, about 6 watts. An explosion would result, however, if the gas collected for, say, 10 minutes recombined. It would liberate energy on the order of $6 \times 600 = 3600$ watt-seconds. If it were a chain reaction occurring in 0.01 seconds, the rate of energy release would be $3600 \div 0.01 = 360,000$ watts or 360 kilowatts.

It is not surprising that recombination occurs; one type of primary cell utilizes the same reaction ($H_2 + \frac{1}{2}O_2 \rightarrow H_2O$) to prevent polarization of the cathode. Vinal [11, page 216 ff.] discusses the reaction at length and points out that the actual reaction is not so simple as shown above, but actually involves several intermediate reactions.

As the experiment proceeded it became evident that statistical methods would be necessary to arrive at valid conclusions from the observed data. A comparison of the first four steady current control runs (step c of the experimental program) showed a disappointing lack of reproducibility of results. Two of these four runs were under suspicion, however. In run number 6, the cathetometer telescope was inadvertently moved during the gassing period and the height of gas in the collecting bottles was there-

These results observed on reduction, his reaction of Fe^{2+} ions
 have been very similar to reduction of Fe^{3+} ions. The present experiment
 demonstrated the reaction; however, the reaction was only slightly lower
 at 20°C. than at 30°C. and only slightly higher at 40°C. The rate
 of reaction is higher than that of Fe^{3+} ions. The reaction of Fe^{2+}
 ions and oxygen to form water. The reaction would not be expected to be
 proceeded continuously, since it would then involve a source of no other
 rate than it was expected, about 6 water. An explosion would result, how-
 ever, if the gas collected for, say, 10 minutes was released. It would then
 also react on the order of $2 \times 1000 = 2000$ millimoles. If it were a chain
 reaction reaction in 0.01 seconds, the rate of energy release would be
 $2000 \div 0.01 = 200,000$ watts or 200 kilowatts.

It is not surprising that reduction occurs; the rate of reduction
 will follow the same reaction $(\text{Fe}^{2+} + \text{H}_2\text{O} \rightarrow \text{Fe}^{3+} + \text{H}_2\text{O})$ to produce polarization
 of the cathode. This [11, page 211] discusses the reaction of Fe^{2+}
 and points out that the actual reaction is not as simple as shown above,
 but actually involves several intermediate reactions.

In the experiment presented it became evident that statistical methods
 would be necessary to arrive at valid conclusions from the observed data.
 A comparison of the first four experiments with the control was made in the
 experimental program) showed a statistically lack of reproducibility of
 results. Two of these four runs were under suspicion, however. In the
 run 6, the photometer telescope was inadvertently moved during the
 counting period and the height of gas in the collecting bottles was there-

fore not accurately measurable. An estimate was made, and the gas evolution computed subject to later acceptance. There was no reason to suspect the duration of charge, ampere-hours, watt-hours, or efficiencies, since the variables involved in these quantities were accurately measured.

Run number 12 was also suspected because the cell voltages on discharge dropped below the low voltage level for that rate. The charging portion of the cycle was completed, nevertheless, and the indices of performance computed. As anticipated, some of the indices differed considerably from those obtained previously.

At this point the investigators considered the advisability of neglecting the dubious results computed in cycles 6 and 12. Since their omission would tend to accentuate the difference between pulsating and steady current performance, the investigators approached the decision with conflicting emotions. On the one hand, there was excellent reason to believe the data to be extraneous. On the other hand, neglecting them would open the investigators to the charge of shutting their eyes to those data which did not confirm their theory. They consequently deferred a decision until a third series of cycles could be run. Unfortunately time did not permit the running of a number of cycles identical to the previous control runs. Instead they conducted 5 similar cycles in which the batteries were discharged at the same rate as before but for a shorter time, 10 minutes instead of 48 minutes. The cells were then charged with a constant, steady current of 2.4 amperes. Data were collected in the same way as before. The means and standard deviations of the various indices of performance were computed.

form not necessarily comparable. As indicated in Table I, the two cycles
 the computer subject to lower acceptance. There was no reason to suspect
 the duration of cycles, subject-holding, or efficiency, since
 the variability involved in these quantities were generally measured.
 For number 12 was also expected because the cell voltage on dis-
 charge dropped below the low voltage level for that rate. The charging
 portion of the cycle was completed, nevertheless, and the indices of per-
 formance compared. As anticipated, some of the indices differed consider-
 ably from those obtained previously.
 At this point the investigators considered the advisability of neglect-
 ing the data on cycles computed in cycles 5 and 12. Since their inclusion
 would tend to accentuate the differences between pulsating and steady current
 performance, the investigators accepted the decision with conflicting e-
 motions. On the one hand, there was excellent reason to believe the data to
 be erroneous. On the other hand, neglecting them would mean the investi-
 gators to the charge of casting their eyes to those data which did not con-
 firm their theory. They consequently deferred a decision until a third
 series of cycles could be run. Unfortunately time did not permit the run-
 ning of a number of cycles identical to the previous control case. Instead
 they conducted 5 similar cycles in which the batteries were discharged at
 the same rate as before but for a shorter time, 10 minutes instead of 25
 minutes. The cells were then charged with a constant, steady current at
 5.4 amperes. Data were collected in the same way as before. The reason
 for standard deviations of the various indices of performance were con-
 sidered.

The assumption seemed reasonable that the second set of control runs should show the same spread of data as the first set. For example, if ampere-hour efficiencies for the second run fell between 80% and 85%, they could be expected to fall within a similar range for the first run. In statistical terminology, it was assumed that the first set of runs comprised a sample from a population having a certain mean and standard deviation. The second set of runs were assumed to comprise a sample of a second population having a different mean but the same standard deviation.

Hoel [6] and Wilks [13], in their discussions of small sample techniques, describe a test for the compatibility of variances. It involves the "F" distribution tabulated by Fisher and Yates [4, table V]. Briefly, the investigators followed this procedure:

1. The first two steady current control runs, numbers 1 and 7, were assumed to be random samples from normally distributed population A having mean μ_A and standard deviation σ_A ; the second set of five, from normally distributed population B having mean μ_B and standard deviation σ_B .

2. It was assumed that $\mu_A \neq \mu_B$, but $\sigma_A = \sigma_B$.

3. An hypothesis H was then made that the dubious runs, numbers 6 and 12, also came from population A.

4. Under hypothesis H, the standard deviation S_A of the first four control runs should be compatible with the standard deviation S_B of the second five runs. This hypothesis was tested by forming the ratio

$$F = \frac{n_A S_A^2 (n_B - 1)}{n_B S_B^2 (n_A - 1)}, \quad \text{where } n = \text{the number of observations (runs) comprising the sample.}$$

The F distribution yields the probability that F

will exceed any given number. Entry into Fisher's tables shows that, under hypothesis H, the probability that $F \geq 4.75$ is only 0.08. Noting that $F \geq 4.75$ for the indices t , V , V/q_f and V/w_f , one rejected the hypothesis H in their cases, but accepted it for Q_c , V_c , η_c and η_w . In other words, the volume data for runs 6 and 12 was rejected because of experimental error.

5. Volume data for runs 6 and 12 were rejected, and new standard deviations S'_A computed for V , V/q_f , and V/w_f . This new value S'_A was found to be compatible with S_B .

6. Even when times for runs 6 and 12 were neglected, the standard deviations of time proved incompatible. Since the curve of duration vs. frequency showed no significant variations, no further statistical analysis of this variable was made.

These computations are tabulated in Figure 12. The mean steady DC values plotted in Figure 10 represent, for time, ampere-hours, and efficiencies, the results of all four control runs. For volume evolved, volume per ampere-hour, and volume per watt-hour they represent the mean only of runs 1 and 7.

The confidence limits for the means were computed by Student's distribution as described in Wilks [13] and Hoel [6.] An unbiased estimate of standard deviation was based on compatible data from the two sets of control runs.

A belated review of Dacos' conclusions showed that lack of reproducibility might have been inferred from his statement that, [3, page 17]

In this test, taken at random from among very numerous observations there is a benefit of 25% in favor of pulsating current. Recall that the mean of all the tests was 18%.

The first part of the paper is devoted to the study of the asymptotic behavior of the sequence of functions $f_n(x)$ defined by the recurrence relation

1. The first step in the process of the investigation is the identification of the problem. This is done by the investigator who is assigned to the case. The investigator will then gather information about the problem and the people involved. This information will be used to determine the cause of the problem and to develop a plan of action.

These conditions are detailed in Table 1. The results are given in Table 2 and Table 3. The results are given in Table 2 and Table 3. The results are given in Table 2 and Table 3.

The following limits for the cases were computed by Student's t -test:

Dacos made no explicit mention, however, of difficulty with spread of results, nor did Vinal's chapter on Tests [12, Chapter IX] warn of this pitfall. Only after considerable grief did the investigators discover what Dacos had implied: that a few large samples would have been preferable to a number of small samples.

Once made no explicit mention, however, of differences with regard of re-
 sults, nor did they's chapter on tests [IX] mention of this
 difficulty. Only after considerable effort did the investigators discover
 that there had indeed: that a few large samples would have been prefer-
 able to a number of small samples.

CHAPTER V

SUGGESTIONS FOR FURTHER INVESTIGATIONS

This experiment raised more questions in the minds of the investigators than it answered. In the first place, it failed to prove precisely which pulsing frequency and shape produce optimum performance; this basic question remains to be solved. It did reveal, however, other questions which must be answered before the solution can be found. It also emphasized related problems and suggested techniques which can simplify and improve experiments with storage batteries. Some of these points are discussed briefly in three categories:

A. Questions whose answers are essential to a solution of the basic question.

B. Questions allied to the basic question.

C. Experimental techniques.

By the "basic question" is meant, "How does battery performance vary with frequency and shape of current pulses?" The discussions below merely highlight the points raised; they are presented as raw observations to be evaluated, ignored, or disproved by subsequent investigators.

A

Questions whose answers are essential to the solution of the basic question.

1. Is storage cell performance truly reproducible experimentally? That is, can all the variables be controlled and/or measured so that identical results can be produced by maintaining identical conditions? What variables are most important?

QUESTIONS AND ANSWERS

This experiment raised some questions in the mind of the investigator. In the first place, it failed to give results which related frequency and shape of the wave form; that is, the question remains to be solved. It is known, however, that questions which must be answered before the solution can be found. It also explained related problems and suggested techniques which can simplify and improve experiments with electric circuits. Some of these points are discussed briefly in three categories:

- A. Questions whose answers are essential to a solution of the basic question.
- B. Questions allied to the basic question.
- C. Experimental techniques.

By the "basic question" is meant, "How does battery performance vary with frequency and shape of current pulse?" The discussion below merely highlights the points raised; they are presented as new observations to be well-related, ignored, or disproved by subsequent investigation.

A

1. Questions whose answers are essential to the solution of the basic question. In this category fall problems involving fundamental principles. That is, can all the variables be controlled and/or measured so that identical results can be produced by repeating identical conditions? What variables are most important?

2. If not, is cell performance a chance variable? If it is a chance variable, is it normally distributed, or does it follow some other distribution? How many times must a given run be repeated to determine the true mean value of a particular index of performance? If the ampere-hour efficiency is determined, say 10 times, can we confidently say that the mean of this ten-fold sample equals the population mean?

3. What wave shape produces optimum performances? Is it a square wave, half sine wave, full-rectified sine wave, or pulsed field wave? What is the optimum duty cycle? (ratio of current-on time to current-off time).

4. Would periodic reversal of charging current improve performance as it has improved electroplating quality?

5. What is the optimum pulse frequency for any given cell?

6. Does pulsing produce beneficial results on cells of all sizes and constructions?

E

Questions allied to the basic question.

1. Does pulsed current produce less electrolysis, or does it merely cause more of the electrolytically generated hydrogen and oxygen to recombine? If the first answer is "yes", ampere-hour efficiencies should be increased. If the second answer is "yes", the volume of escaping gas should be less, while ampere-hour efficiencies would remain unchanged.

2. Can indices of performance be related analytically to pulse shape and frequency, possibly by transient analysis?

3. If not, is still performance a good indicator? If it is a
 choice variable, is it normally distributed, or does it follow some other
 distribution? How many times was a given test repeated in laboratory
 the time mean value of a particular kind of performance? Is the subject-
 hour efficiency is measured, say 10 times, and we consistently get that
 the mean of this test-tail equals the population mean?

4. What were those problems outlined previously? Is it a
 given wave, half sine wave, full-sine wave, or raised half
 wave? What is the optimum duty cycle (ratio of on-time-on time to on-
 time-off time)?

5. Would periodic reversal of coupling current improve perfor-
 mance as it has improved electrostatic quality?
 6. What is the optimum pulse frequency for any given call?
 7. Does raising voltage potential results on calls of all

size and construction?

B

Questions allied to the basic question.

1. How raised current produce less distortion, or does it
 merely cause more of the electrically generated harmonic and super-
 to resonance? Is the first order is good, super-harmonic efficiencies
 should be increased. If the second order is good, the volume of equip-
 ing and should be low, while super-harmonic efficiencies would remain un-
 changed.

2. For indices of performance as related qualitatively to pulse
 shape and frequency, possibly by transient analysis?

3. If a test cell consisting of two plates, widely separated, were charged with pulsating current and the gas from the respective plates collected separately, would performance be improved?

4. Is "shedding" of active material a function of total gas formed or only of that fraction of the gas which escapes without recombining into water?

C

Experimental techniques.

1. The use of recording instruments, either in addition to or in lieu of indicating instruments, would simplify the problems of recording data, computing results, and regulating charging current. Esterline Angus recording milliammeters could be connected to measure cell voltages and charging current. Several advantages would be:

a. Continuous data record, rather than only a periodic record. This feature would allow closer determination of the time of end of charge than would the constancy of two successive readings separated by a time interval.

b. Elimination of time-consuming reading and logging.

c. Quick computation of time-average values, such as voltages, by planimeter, and quick and accurate determination of time rates.

d. Elimination of need for extremely accurate current regulation. In the present experiment, current had to be maintained exactly constant to permit accurate determination of ampere-hours as the product of current and time. If ampere-hours could be determined by planimeter,

1. It is not only a matter of fact, but a matter of principle, that the records of the various departments of the Government should be kept in a systematic and orderly manner, and that the records of the various departments should be kept in a systematic and orderly manner, and that the records of the various departments should be kept in a systematic and orderly manner.

2. It is not only a matter of fact, but a matter of principle, that the records of the various departments of the Government should be kept in a systematic and orderly manner, and that the records of the various departments should be kept in a systematic and orderly manner, and that the records of the various departments should be kept in a systematic and orderly manner.

3

3. It is not only a matter of fact, but a matter of principle, that the records of the various departments of the Government should be kept in a systematic and orderly manner, and that the records of the various departments should be kept in a systematic and orderly manner, and that the records of the various departments should be kept in a systematic and orderly manner.

4. It is not only a matter of fact, but a matter of principle, that the records of the various departments of the Government should be kept in a systematic and orderly manner, and that the records of the various departments should be kept in a systematic and orderly manner, and that the records of the various departments should be kept in a systematic and orderly manner.

5. It is not only a matter of fact, but a matter of principle, that the records of the various departments of the Government should be kept in a systematic and orderly manner, and that the records of the various departments should be kept in a systematic and orderly manner, and that the records of the various departments should be kept in a systematic and orderly manner.

6. It is not only a matter of fact, but a matter of principle, that the records of the various departments of the Government should be kept in a systematic and orderly manner, and that the records of the various departments should be kept in a systematic and orderly manner, and that the records of the various departments should be kept in a systematic and orderly manner.

slight variations in current would be permissible.

e. The higher inertia of recording instruments would give them a better integrating characteristic than indicating instruments. The ballistic galvanometer for current metering might prove unnecessary.

2. Since individual cell performances for a given cycle were averaged, time could be saved by metering battery voltage and gas rather than individual cell values. In this way a large number of cells could be used, rather than only three, and more reproducible mean data might result.

3. The development of a recording device for volume of evolved gas would facilitate data collection.

4. Most important of all, a number of observations should be made at each frequency at which performance is to be determined accurately. Student's distribution shows that the confidence limits for a population parameter are narrowed as the number of observations is increased. Qualitatively this means that the average of the observed data for a number of runs approaches the true value as the number of runs approaches infinity. Note that the number of observations can be increased either by repeating runs or by connecting more cells in series.

5. Bearing in mind the perversity of storage batteries in failing to behave reproducibly, the investigator should heed Hoel's warning: [6, page 215]

Too many experimenters do not seem to appreciate the obvious injunction that the time to design [statistically] an experiment is before the experiment is begun.

A study of Hoel's Chapter XII on "Statistical Design in Experiments" should assist in planning a valid and efficient experiment.

light variations in current would be negligible.

4. The higher limits of recording duration would give more a better indication of the effect of the treatment. The plastic galvanometer for current recording might prove unsatisfactory.

5. Since individual cell performance for a given cycle was measured, time could be saved by measuring battery voltage and the number of individual cell values. In this way a large number of cells could be read, rather than only three, and more reproducible mean data might result.

6. The development of a recording device for values of voltage and current would facilitate data collection.

7. Most important of all, a number of observations should be made of each frequency at which performance is to be determined separately. Student's distribution shows that the confidence limits for a population parameter are normal as the number of observations is increased. Qualitative if this means that the average of the observed data for a number of runs approaches the true value as the number of runs approaches infinity. Note that the number of observations can be increased either by repeating runs or by connecting more cells in series.

8. Finding in mind the possibility of storage batteries is falling to behave reproducibly, the investigator should read Noel's warning: [6, page 212]

Too many experiments do not seem to appreciate the obvious instruction that the time to design [statistically] an experiment is before the experiment is begun.

A study of Noel's Chapter III on "Statistical Design in Experiments" should assist in planning a valid and efficient experiment.

CHAPTER VI

CONCLUSION

The experiment, while it failed to produce the quantitative results hoped for, demonstrated qualitatively that battery performance is improved by charging with pulsating current. For the Willard WB-24-2 cell a frequency on the order of 0.5 to 1 cycle per second produced best results within the frequency range covered. Further investigation, utilizing the tools of statistics, is necessary to determine the reason for this improvement and to determine optimum pulse shape and frequency for this and other cells. There is reason to believe that low frequencies are superior to high frequencies. The investigators consider their time and efforts justified since their results not only supplement the meager knowledge about pulse-charging but also point the way for future study.

APPENDIX A

EXPERIMENTAL SETUP

The experimental setup was designed to (1) permit close control of charge and discharge currents, and to provide a choice of currents for charging; (2) provide for metering or measuring charge and discharge currents, time of charge and discharge, and individual cell voltages, temperatures, and gas evolved; (3) provide protection against accidental "reverse current" discharge of the cells; and (4) provide a stable power supply, arranged for a minimum of interruptions or disturbances to the primary power source. A brief explanation of each of these provisions will indicate the methods and principles involved and will provide a clear picture of the overall setup. In the interests of completeness, a block diagram with descriptions, and an overall circuit diagram are included.

1. Current control.

Since ampere-hour meters were unavailable, constancy of current, on both charge and discharge, was essential to the outcome of the experiment. Regulation of charging current was accomplished by the use of automatic, thermal type, variable resistance, "constant current" ballast tubes, Amperite type A-10. Characteristics of these tubes are shown in Figure 13. These tubes are designed to hold current constant to $\pm 2\%$. Supplementary rheostats were provided for very fine control, permitting excellent overall maintenance of constant current.

On discharge, the voltage of the battery alone was below the minimum operating voltage of the Amperite ballast tubes, so that discharge

TITLE DEPARTMENT

[illegible]

1. Control

[illegible]

On October 1, 1944, the voice of the speaker was heard below the line.

A. Comparison of Amperite and other resistors

B. Characteristics of A-10 series

FIGURE 13. VOLT-AMPERE CHARACTERISTICS OF A PERITE BALLAST TUBES

current was necessarily controlled by rheostats only. Adequate control of discharge current was realized, but the rheostats required constant manipulation by the operator in order to maintain constant current.

Constant current requirements for charging included (a) a starting rate source of 6 amperes steady direct current, and for the finishing rate, (b) 2.4 amperes steady direct current, or (c) 2.4 amperes (average) pulsating direct current of square waveshape, at 4.8 amperes peak value, at frequencies from 0.5 to 8 cps, obtained from a motor driven, cam operated timer switch, or (d) 2.4 amperes pulsating direct current obtained through a half wave rectifier bank from an alternator, at frequencies from 20 to 400 cps. Of this last item, it may be said that waveshape was beyond control, since the investigators were obliged to use whatever sundry alternators that were available for this wide range of frequencies, but in any case, current was maintained at the proper average value.

2. Mensuration

The problem of metering appeared to be quite difficult at first, especially at pulsing rates below about 40 cps, where ordinary d'Arsonval movements tended to follow the current excursions rather closely, so rendering them useless for "average current" indications. In the case of current metering, when the motor driven timer switch was used, it was also necessary to consider that, although the "on" current value might be precisely 4.8 amperes, the "on" and "off" times very probably were not exactly equal*, so that the average current could not be assumed to be precise-

*This assertion was later borne out by a graphical recording of waveshape on a "Brush" recorder.

current was necessarily controlled by the operator only. A constant current of discharge current was required, but the discharge current was constant manipulation by the operator in order to maintain constant current. Constant current requirements for discharge included (a) a steady rate source of 6 pulses steady direct current, and for the fishing rate, (b) 5.4 pulses steady direct current, or (c) 5.4 pulses (average) pulsing direct current of square wave pulse, at 1.8 pulses peak value, at frequencies from 0.5 to 8 cps, obtained from a motor driven, can operate either switch, or (d) 5.4 pulses pulsing direct current obtained through a half wave rectifier bank from an alternator, at frequencies from 30 to 100 cps. Of this last item, it may be said that whatever was beyond control, since the investigators were obliged to use whatever energy alternators that were available for this wide range of frequencies, but in any case, current was obtained at the proper average value.

5. Discussion

The problem of metering appeared to be quite difficult at first, especially at pulsing rates below about 10 cps, where ordinary 1:1000 movement needed to follow the current movement rather closely, so that during these periods for "average current" indication. In the case of direct metering, when the motor driven timer switch was used, it was also necessary to consider that, although the "on" current value might be precisely 1.8 pulses, the "on" and "off" times very probably were not exactly equal*, so that the average current could not be assumed to be precisely

*This assertion was later borne out by a precision recording of waveform on a "Rohm" recorder.

ly 2.4 amperes. Thus, a meter which would average, or integrate, was required, and a long period, ballistic galvanometer, connected to a very low resistance shunt, provided the solution. The low resistance shunt caused the instrument to be highly overdamped, thus adding to its integrating ability. An instant acting relay arrangement was provided, whereby the galvanometer and its associated shunt could be switched into either the battery charging circuit, or into a constant current reference circuit, maintained accurately at 2.40 amperes, for purposes of zero-setting and comparison.

When charging with steady direct current, or with rectified alternating current at frequencies of 40 cps and higher, ordinary d'Arsonval type ammeters were used, and provided satisfactory current indications. It is noteworthy that the precision of every electrical meter reading which might directly influence the quantitative experimental results was enhanced by the use of magnifying glasses placed over the meter scales.

Voltages were read to three decimals with a 0-3 volt scale voltmeter, provided with a switch for selecting any one cell voltage. To prevent the voltmeter pointer following the "voltage fluctuation" across the cells, during pulsing at rates below 40 cps, which would result in inaccurate voltage readings, a switching arrangement was provided so that the cells could be switched to a steady direct current charging source at 2.4 amperes for the duration of the meter readings.

While it is realized that voltages read to three decimals with an ordinary d'Arsonval voltmeter movement would be subject to suspicion

In 2.4 ampere. Then, a meter which would average, or integrate, the re-
 sponse, and a lamp meter, ballistic galvanometer, connected to a very low
 resistance shunt, provided the solution. The low resistance shunt caused
 the instrument to be highly overdamped, thus adding to the integration ef-
 fect. An internal timing arrangement was provided, whereby the
 galvanometer and its associated shunt could be switched into action the
 battery charging circuit, or into a constant current reference circuit,
 maintained accurately at 2.40 ampere, for purposes of re-zeroing and
 comparison.

When charging with steady direct current, or with rectified al-
 ternating current at frequencies of 40 cps and higher, ordinary D'Arsonval
 type meters were used, and provided satisfactory current indications. It
 is noteworthy that the precision of every electrical meter reading which
 might directly influence the quantitative experimental results was enhanced
 by the use of multiplying glasses placed over the meter scales.

Voltages were read to three decimals with a 0-1 volt scale volt-
 meter, provided with a switch for selection of any one cell voltage. To pre-
 vent the voltmeter pointer following the "voltage fluctuation" across the
 cells, during pulsing at rates below 40 cps, which would result in inaccu-
 rate voltage readings, a switching arrangement was provided so that the
 cells could be switched to a steady direct current charging source at 2.4
 amperes for the duration of the meter reading.

While it is realized that voltmeters read to three decimals with
 an ordinary D'Arsonval meter movement would be subject to magnifica-

as to the absolute accuracy of the third decimal, values were nevertheless read as closely as possible, with the aid of the magnifying glass placed over the scale. The prime purpose of the voltage readings was to ascertain the point of completion of charge, based on the fact that voltage across the cell reaches a maximum at the end of charge and thereafter decreases slightly. Thus, even though the absolute magnitude of voltage may have been slightly in error, the method used enabled the operator to determine quite closely the end-of-charge point, inasmuch as the previously mentioned voltage decrease was easily discernible. It is well to note that a "set of voltage readings", as taken periodically during the finishing rate charge, consisted of three separate readings, one for each cell. In switching the voltmeter from cell to cell, its pointer momentarily swung toward zero, during the switching period, so that for each cell voltage reading, the pointer always approached its steady state position from the same direction. Any lost motion was therefore always in the same direction.

Time was reckoned by an electric timer connected to be energized automatically whenever the cells were connected to either the charge or discharge circuit.

Temperature of each cell was obtained by means of a Fahrenheit thermometer sealed into the filling cap, with the thermometer bulb immersed in the cell electrolyte.

Temperature of the evolved gas was obtained with a Centigrade thermometer inserted into the gas collecting vessel of one cell, by way

[illegible]

of a pilot or sample temperature determination. The investigators felt that elimination of thermometers in the other two gas collecting vessels was justified, since the three vessels were grouped closely together, and therefore subject to essentially the same changes in ambient temperature, which proved to be the major factor in determining gas temperature. Further, the two investigators were required to make 11 readings within the space of about 30 seconds every 6 minutes, so that elimination of all unnecessary readings was highly desirable.

Evolved gas from each cell displaced an equivalent volume of water from a calibrated glass vessel. The level of the remaining water in each vessel was accurately determined periodically with a cathetometer.

3. Reverse Current Protection

Inclusion of this device in the charging circuit was necessary to prevent accidental discharge of the cells through the generator armature, in the event of a power failure. The reverse current relay (Figure 14) was connected to be normally energized, through a disc rectifier; thus, the relay was energized only when current was flowing in the proper (charging) direction. Voltage to operate this relay was obtained from the IR drop across a resistance in series with the charging circuit. If, for any reason, the cells commenced to discharge through the charging circuit, the rectifier prevented current flow through the relay coil and caused the contacts to drop out. Deenergization of this relay simultaneously opened the cell circuit, stopped the electric timer clock, and shut down the motor-generator set, after which manual resetting was necessary.

of a glass or some transparent substance. The investigation of the elimination of the water in the other two glass vessels was facilitated, since the glass vessels were covered of glass, and therefore subject to essentially the same extent of radiant transmission, which proved to be the major factor in determining the temperature. Then, the two investigations were repeated in which the space of about 30 centimeters every 5 minutes, as the elimination of all the necessary conditions was being established.

Indeed, the fact that each of the two vessels of

water from a calibrated glass vessel. The level of the remaining water in each vessel was accurately determined optically with a hydrometer.

2. General Observations

Observations of this kind in the chemical field are necessary in

proving scientific statements of the value of the chemical substance.

In the case of a pure liquid, the liquid is pure (Figure 10)

was connected to an auxiliary circuit, through a coil resistor, and

the relay was connected with some current and the relay is the proper shape-

less, electrical. The relay is connected with the relay and the relay is

shown a resistance in series with the relay circuit. It, for any reason,

the relay is connected to the relay circuit, the relay circuit, the resistor

provided with the relay and the relay and the relay is connected to

the relay. The relay is connected to the relay and the relay is connected to

only, through the relay circuit, and the relay is the relay-circuit

rel, after which the relay circuit was necessary.

Figure 14. Reverse current relay detail.

4. Power Supply

In order to insure a minimum of interruptions or disturbances to the charging current and auxiliary apparatus (clock, motor driven timer switch, etc.), a primary power source of high capacity was desired. The system used was the largest capacity system available in the laboratory, viz., the 230 volts, 3 phase, a. c. distribution system. A transformer provided 115 volts, single phase, where needed. An oversized motor-generator set provided a stable source of charging current. This source sufficed for both the steady charging currents and the 0.5 to 8 cps pulsating direct current for charging. Alternating current for charging, from 20 to 100 cps, was supplied by a motor driven alternator, with the motor connected to a "Ward-Leonard" generator system for speed control. 400 cps alternating current was obtained from a 1.8 KVA voltage regulated, motor driven, 400 cps alternator.

5. Detailed Description of Components

The overall provisions of the experimental setup have been set forth above, followed by several explanatory paragraphs on the salient features of the apparatus. A detailed, functional description of component parts follows.

Referring to Figure 15, note that three basic arrangements of the apparatus were required. Figure 15A shows the arrangement where only steady direct current was required for charging. This arrangement was employed for the starting rate charge during every cycle, and for the finishing rate charge during the control cycles (q.v.), and was the basic arrangement, to

which modifications were made as necessary for pulsating charges, as shown in Figure 15B and C.

The generator was a 2 KW, 32 volt, 62.5 ampere machine, driven by a 15 HP induction motor, and sufficient in capacity to show negligible regulation under the relatively light charging load. Some ripple of 540 cps was discernible in the output of this machine, but the percentage of ripple voltage was negligibly small.

Two parallel connected rheostats were employed, supplementary to the current regulating ballast tubes, as previously described. Rheostat values were 4 ohms and 25 ohms, the former serving as a coarse control, the latter as a fine control.

The voltmeter arrangement for metering individual cell voltages was described above. Switch details are shown in Figure 16. Separate leads were run from the terminals of this switch direct to the actual terminals of each cell, rather than to the "battery" terminals, to eliminate any IR drop inherent in the latter terminals, by virtue of their carrying either charge or discharge current.

The reverse current protective device and the bank of Amperite current regulating tubes were previously described in this appendix. Of the Amperite ballast tubes it is worth saying that they were procured in three sizes, viz., 2-A-10, 5-A-10, and 9-A-10, having nominal current ratings of 0.2, 0.5, and 0.9 amperes, respectively. Suitable combinations of these tubes in parallel gave the various desired charging current values.

In Figure 15B, the galvanometer current metering circuit, a cur-

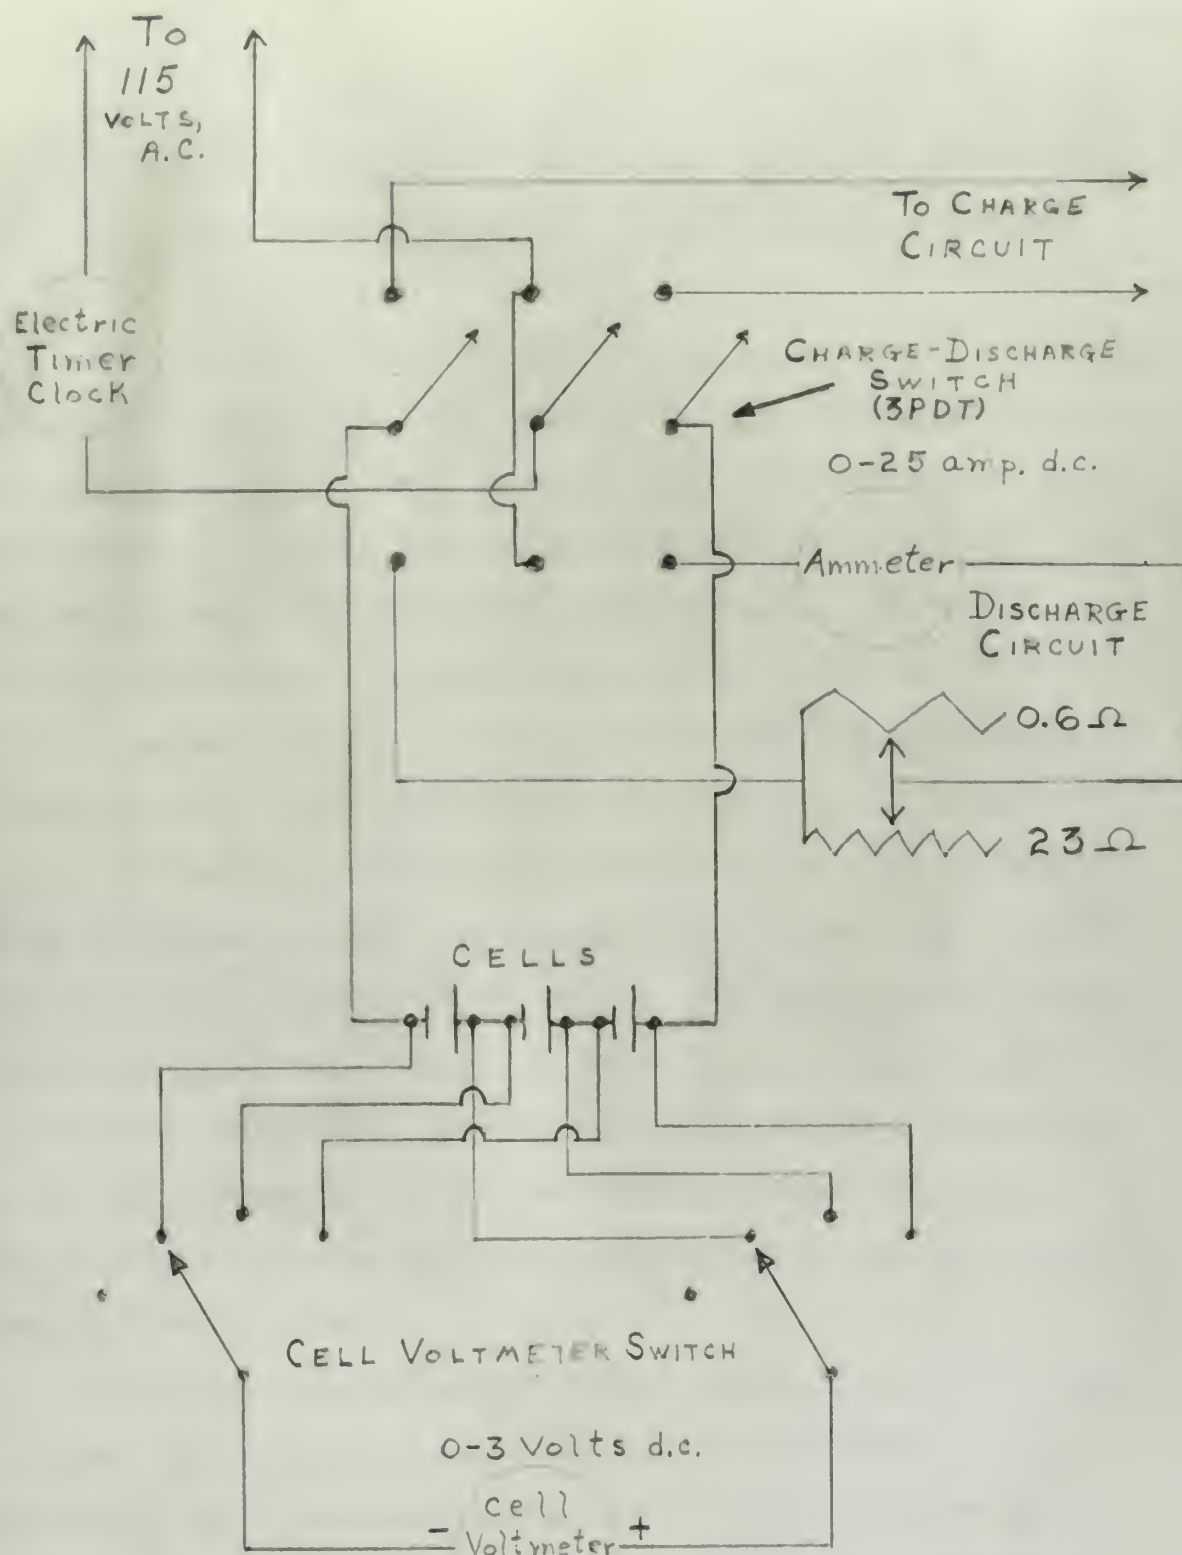

Figure 16. Cell voltmeter switch detail.

rent selector switch, a motor driven, cam operated pulser, or timer switch, an additional bank of Amperite tubes, and additional rheostats have been added.

The galvanometer circuit detail is shown in Figure 17. The galvanometer and its purpose have been described earlier. The associated relay was controlled from the galvanometer position, and permitted switching of the galvanometer from the cell charging circuit to the reference current circuit, while maintaining continuity of these circuits. The reference current circuit consisted of a source of direct current at 250 volts (obtained from a 5 KW generator, tandem coupled to the main induction motor and 32 volt generator set), a 2.4 ampere bank of Amperite tubes, a 0-3 ampere ammeter, two parallel connected rheostats of about 25 ohms each, and sufficient series resistors to limit the current to the desired value. Current in this circuit was maintained at 2.4 amperes. The galvanometer scale was not calibrated in amperes. Rather, the pointer was set to give zero deflection when the galvanometer was connected in the reference current circuit; then the galvanometer was switched into the charging circuit, and charging current adjusted to again give zero deflection, corresponding to 2.4 amperes average current.

The current selector switch, shown in detail in Figure 18, enabled the operator, in one switching operation, to choose 2.4 amperes of (1) steady current, or (2) pulsating current, at a frequency generated by and preset in the motor driven timer switch. The purpose of the steady current source was described under "Mensuration".

The heart of the low frequency, pulsating current generating device was the motor driven, cam operated timer switch shown in Figure 19.

rent selector switch, a motor driven, can operate either, or both switch, an additional bank of superimposed tubes, and additional rheostats have been added.

The galvanometer circuit detail is shown in Figure 17. The galvanometer and its purposes have been described earlier. The associated relay was controlled from the galvanometer position, and provided switching of the galvanometer from the cell charging circuit to the reference current circuit, while maintaining continuity of these circuits. The reference current circuit consisted of a source of direct current at 250 volts (obtained

from a 5 KW generator, tandem coupled to the main induction motor and 25 volt generator set), a 5.0 ohm bank of superimposed tubes, a 0-3 ohm rheostat, two parallel connected rheostats of about 25 ohms each, and a milliammeter, which was used to limit the current to the desired value. Current in this circuit was maintained at 2.4 amperes. The galvanometer scale was not calibrated in amperes. Instead, the pointer was set to give zero deflection when the galvanometer was connected in the reference current circuit; then the galvanometer was switched into the working circuit, and charging current adjusted to again give zero deflection, corresponding to 2.4 amperes average current.

The current selector switch, shown in detail in Figure 18, supplied the operator, in one switching operation, to choose 2.4 amperes or (1) steady current, or (2) pulsating current, at a frequency generated by and present in the motor driven alternator. The purpose of the steady current source was assigned water "distillation".

The heart of the low frequency, pulsating current generating device was the motor driven, can operate either switch shown in Figure 19.

Figure 17. Galvanometer circuit detail.

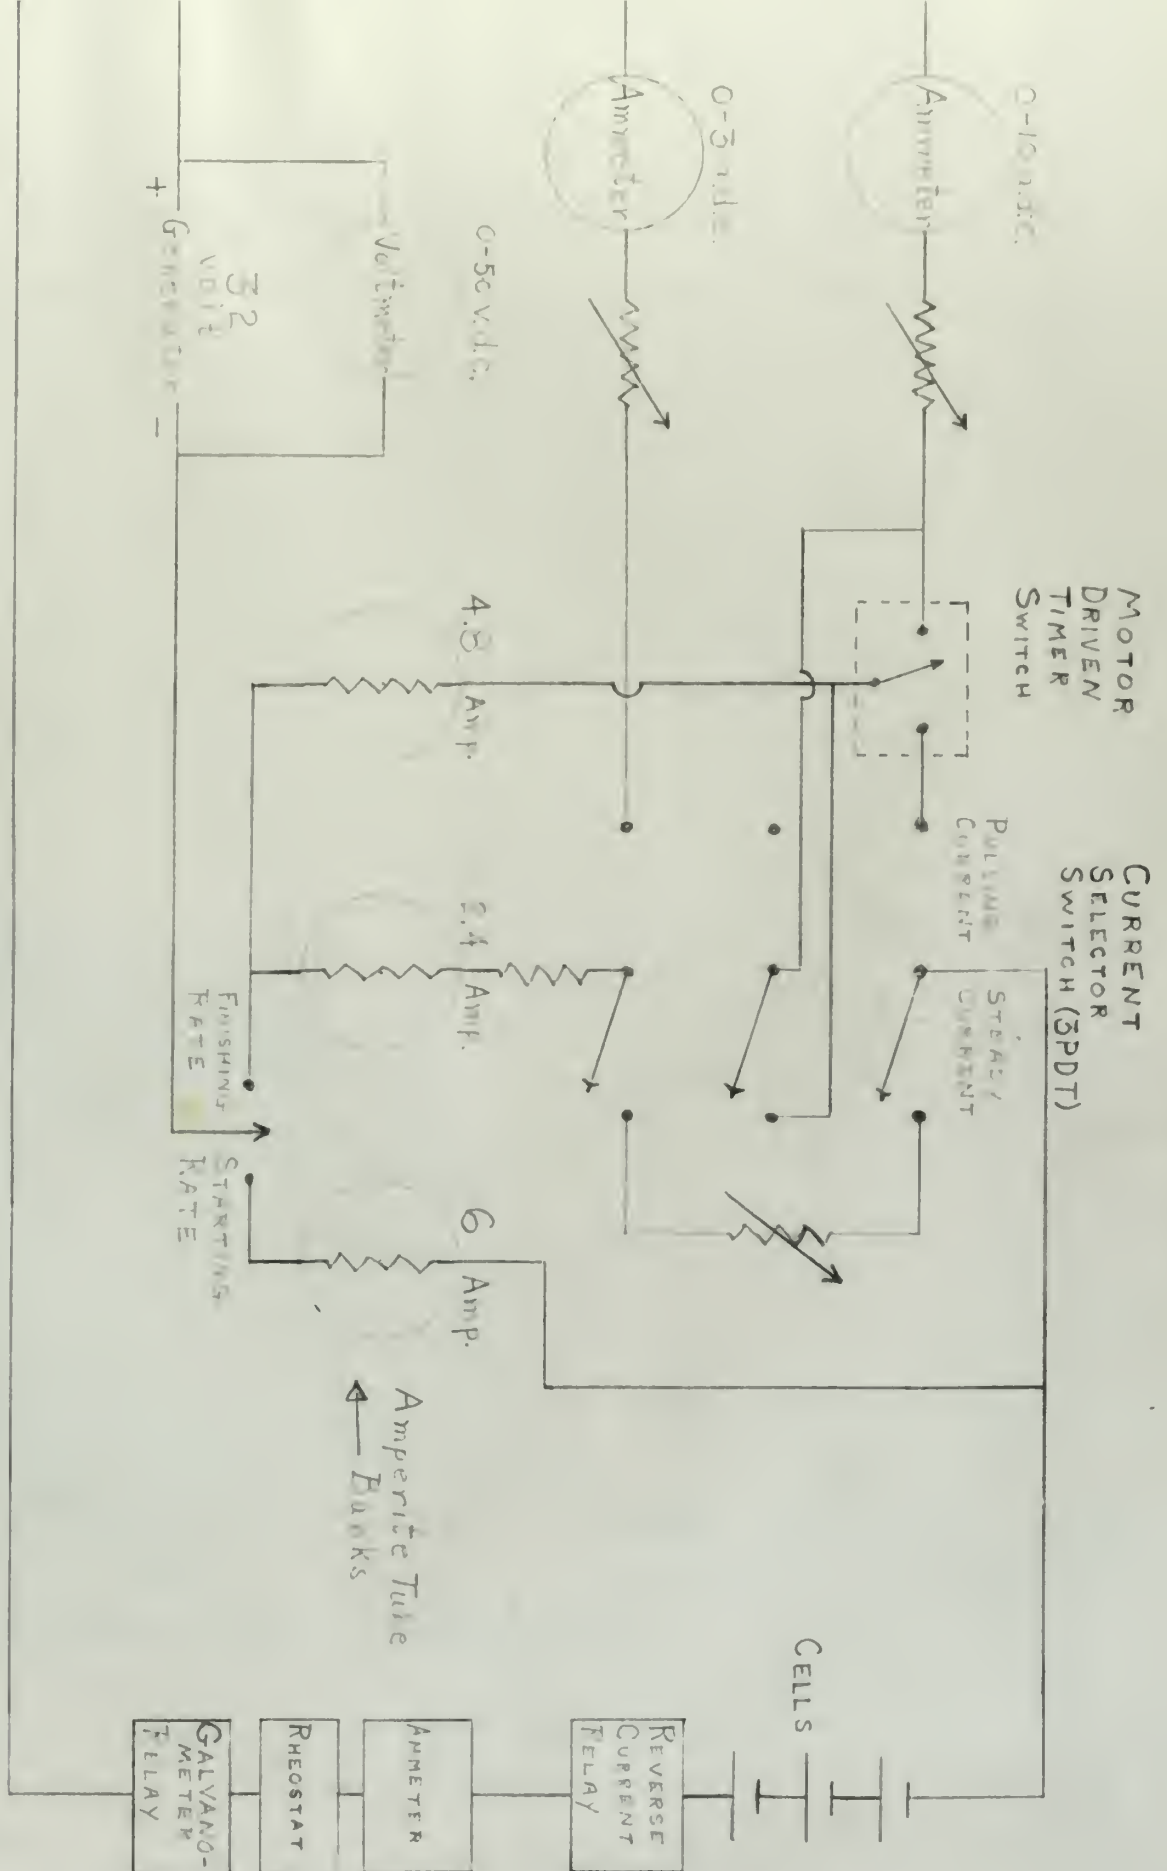

Figure 18. Current selector switch detail.

Comprising this was a fractional horsepower induction motor driving a simple cam through a variable ratio gear train. The cam actuated a microswitch once during each revolution. The microswitch in turn energized the coil of a locking type stepping relay, with single pole, double throw contacts. The stepping relay construction was such that its contacts threw to one position or the other with each energization of the coil, and remained locked in that position until a subsequent energization of the coil. In one position the circuit to the cells was completed through the 4.8 ampere Amperite bank. In the other, the cell circuit was opened, and the Amperite tubes were switched to a rheostat and ammeter, leading back to the generator. Thus, the cells alternately received either 4.8 amperes or no current, giving an average current of 2.4 amperes, as required. The speed range of the cam permitted a pulsating current frequency range of about 0.2 to 5 cps. It was discovered that the stepping relay arrangement was unsuitable for frequencies above about 2 cps, however, so that for the runs at 3 and 7.8 cps, an additional microswitch and cam were installed, the microswitch, with single pole, double throw contacts, being substituted circuit-wise for the contacts of the stepping relay. The cam operated this microswitch every 180° of rotation, extending the frequency range of the device to an upper limit of about 10 cps.

The resistance of an Amperite ballast tube varies with temperature in much the same manner as does that of an ordinary incandescent lamp, except that the thermal time constant of the Amperite tube is longer. Due to this thermal characteristic of the Amperite tubes, it was found necessary to cause the desired value of current to flow through them continuously in

Comparison with a functional frequency selective motor system
single one through a variable ratio gear train. The gear ratios are
within one half and one. The mechanism is now arranged so
coil of a locking type winding relay, with single coil, double three con-
tacts. The winding relay mechanism was such that the contacts move
to one position or the other with each energization of the coil, and re-
turned back to the position with a subsequent energization of the coil.
In one position the circuit to the coil was completed through the 2.5
ohm inductive load. In the other, the coil circuit was opened, and the
inductive load was released by a shunt and resistor, leading back to
the generator. Thus, the ratio of inductance varied either 2.5 ohms or
no current, giving an average current of 2.5 ohms, as required. The
speed ratio of the motor was a variable current frequency ratio of
about 0.5 to 2 cps. It was determined that the winding relay mecha-
nism was suitable for frequencies from about 2 cps, however, so that
for the runs at 7 and 1.5 cps, an additional shunt resistor was used in-
stead, the shunt resistor, with single coil, double three contacts, being
energized directly for the contacts of the winding relay. The com-
parison was observed every 10% of rotation, extending the frequency
range of the motor to an upper limit of about 10 cps.
The operation of an inductive load with a variable ratio
ratio in such a way as to give an average current of 2.5 ohms, as
except that the motor was energized by the winding relay. The
to this point characteristic of the winding relay, it was found necessary
to make the winding ratio of motor to flow through the mechanism is

order to realize optimum current regulation. Thus, the 4.8 ampere bank of Amperite tubes was switched alternately from the cells to the previously mentioned rheostat and ammeter circuit back to the generator, the rheostat being adjusted to give an ammeter reading of 4.8 amperes, so that 4.8 amperes flowed through these Amperite tubes continuously. A similar arrangement was provided for the 2.4 ampere bank of Amperite tubes, used for obtaining steady current for purposes of voltage metering. The current selector switch connected this bank either into the cell circuit, or to a rheostat and ammeter circuit returning to the generator. Whenever the 2.4 ampere circuit was switched to the cells for a voltage reading, the motor driven timer switch contacts were short circuited, so that for this position of the current selector switch, the associated 4.8 ampere bank of ballast tubes was continuously connected to its rheostat and ammeter return circuit, independent of the timer switch.

In Figure 15C, the variable frequency alternator, thyatron rectifier bank, and associated Amperite tube bank have replaced the motor driven timer switch of Figure 15B, with other features remaining essentially the same. At frequencies of 40 cps and greater it was unnecessary to use the galvanometer for metering of current, since ordinary d'Arsonval type meters gave satisfactory results at these frequencies. Three General Electric type FG-95 thyatron tubes connected in parallel were used to half-wave rectify the alternator output. No attempt was made to utilize the unique characteristics of the thyatron tubes. Indeed, any rectifier of suitable current carrying capability would have served the purpose. The one outstanding advantage of the particular thyatrons employed was their immediate availa-

order to realize optimum current regulation. Thus, the 2.5 ampere bank of reactive tubes was switched alternately from the cells to the generator. It was then possible to transfer current back to the generator, the flow of power being in line with a constant reading of 1.5 amperes, so that 2.5 amperes flowed through these reactive tubes continuously. A similar arrangement was provided for the 2.0 ampere bank of reactive tubes, and for physical steady current for purposes of voltage regulation. The current collector which connected this bank either into the cell circuit, or to a rheostat and thence directly to the generator. However, the 1.5 ampere circuit was switched to the cells for a voltage reading, the motor driven from which was connected to the generator, so that for this position of the reactor selector switch, the associated 1.8 ampere bank of half-wave tubes was continuously connected to the rheostat and motor selector circuit, independent of the reactor switch.

In Figure 15C, the variable frequency of generator, frequency transformer bank, and associated reactive tube bank have replaced the motor driven reactor bank of Figure 15B, with other features remaining essentially the same. At frequencies of 40 cps and greater it was unnecessary to use the transformer for reduction of current, since directly connected from motor drive satisfactory results were obtained. These General Electric type 60-25 reactors were connected in parallel with each other to supply the reactor bank. No attempt was made to utilize the motor characteristic of the reactor bank. Indeed, the utilization of suitable current carrying capability was not even considered. The one interesting feature of the reactor bank was the immediate switching of the reactor bank.

bility to the investigators. At the frequencies involved here (20 cps and above) it was found unnecessary to consider the thermal delay inherent in the Amperite tubes, and no auxiliary switching arrangement was provided for the purpose.

6. Gas Collecting Apparatus

The gas collecting apparatus consisted of 3 one gallon, round glass jugs, one connected to each cell and, through a pressure equalizing flask, to an over-flow reservoir, by rubber tubing, as shown in Figure 20. Gas from a cell displaced an equal volume of water from its associated jug. Pressure within each jug was reduced to atmospheric prior to each reading, by matching the water levels of the jug and its equalizing flask. Height of liquid in the jug was read to 0.01 cm with a cathetometer. Cross sectional areas of the jugs were sufficiently linear over the operating range to permit the use of a constant term in computing volume of water displaced, as, for example, 200 cc per cm. Gas volume was temperature corrected to 27° C.

SAMPLE CYCLE ANALYSIS SHEET

Discharge

Current (I_d) - Constant at 15 amperes throughout discharge.
 Mean Voltage (V_{md}) - Time weighted mean voltage, from voltage readings made every 6 minutes throughout discharge.
 Duration (t_d) - Duration of discharge in hours.
 Ampere-hours (Q_d) - Product of I_d and t_d .
 Energy (W_d) - Product of I_d , V_{md} and t_d .

Charge - Starting Rate

Current (I_s) - Constant at 6.02 amperes throughout starting rate charge.
 Mean Voltage (V_{ms}) - Time weighted mean voltage, from voltage readings made every 12 minutes throughout starting rate charge.
 Duration (t_s) - Duration of starting rate charge in hours.
 Ampere-hours (Q_s) - Product of I_s and t_s .
 Energy (W_s) - Product of I_s , V_{ms} and t_s .

Charge - Finishing Rate

Current (I_f) - Constant average value throughout finishing rate charge.
 Mean Voltage (V_{mf}) - Time weighted mean voltage of finishing rate charge.
 Duration (t_f) - Duration of finishing rate charge in hours.
 Ampere-hours (Q_f) - Product of I_f and t_f .
 Energy (W_f) - Product of I_f , V_{mf} and t_f .

Gas

Height (h) - Difference in height in centimeters of water in gas collecting vessel at beginning of finishing rate charge and end of finishing rate charge.
 Area (A) - Cross sectional area of gas collecting vessel in square centimeters.
 Volume (V') - Volume of water displaced from gas collecting vessel during finishing rate charge - product of A and h .
 Temperature (T) - Gas temperature at end of finishing rate charge, °C.
 Volume (V) - V' corrected for T to a datum of 27°C, or 300° Kelvin (Centigrade, absolute).
